Basic Pathobiology of the Eye and Its Complications

Elia J. Duh

Lloyd P. Aiello

INTRODUCTION

Diabetic retinopathy, a common ocular complication of diabetes mellitus, is the leading cause of blindness in working-age Americans.¹⁻³ In fact, diabetic retinopathy accounts for 12% of all new cases of blindness in the United States and there are an estimated 148,000 individuals in whom sight-threatening stages of retinopathy occur each year. Indeed, the risk of ocular disease in patients with diabetes is 25 times that of the general population.⁴ The prevalence of diabetic eye disease has dramatically increased over the past 40 years, in part due to improvements in managing diabetes that have dramatically extended the life span of these patients.⁵

The mechanisms underlying diabetic retinopathy have been the subject of extensive research for over half a century. Particularly over the last decade, our understanding of the mechanisms of both nonproliferative and proliferative diabetic retinopathy has advanced significantly. These achievements not only improve our knowledge of the basic pathobiology underlying diabetic retinopathy, but also set the stage for the development of novel therapeutic strategies promising significant improvements in clinical care for patients with diabetes.

CLINICOPATHOLOGIC CHANGES IN DIABETIC RETINOPATHY

Diabetic retinopathy is clinically divided into two stages, nonproliferative diabetic retinopathy (NPDR) and proliferative diabetic retinopathy (PDR). However, even before retinopathy becomes clinically apparent, histopathologic changes occur. The earliest known changes are capillary basement membrane thickening (associated with a change in its chemical composition),⁶ the loss of the retinal endothelium-supporting pericytes,^{7,8} and alterations in retinal blood flow.⁹ Pericyte loss potentially contributes to the subsequent formation of microaneurysms (Fig. 40-1) due to weakening of the vessel wall¹⁰ and may also contribute to neovascularization due to the loss of the pericyte's inhibitory effect on endothelial cell growth.¹¹ Several studies have demonstrated a decrease in retinal blood flow even before retinopathy is clinically apparent^{9,12-15} and retinal blood flow increases as diabetic retinopathy progresses.^{13,16,17} Autoregulation of retinal blood flow is also significantly impaired before retinopathy becomes clinically apparent.¹⁸⁻²⁰

With disease progression, the clinical signs of nonproliferative diabetic retinopathy appear.⁵ The classic signs of NPDR include

retinal microaneurysms, dot and blot retinal hemorrhages, cotton-wool spots representing infarctions of the nerve fiber layer (Fig. 40-2), venous loops, venous beading, retinal capillary dropout, and intraretinal microvascular abnormalities (IRMAs). Essentially all patients with diabetes will eventually develop NPDR as the incidence approaches 100% after 15 years of disease.^{21,22} With the development of NPDR, retinal blood flow begins to increase.^{13,16,17}

As NPDR advances, retinal capillary dropout arises, resulting in progressive retinal ischemia. The ischemic retina produces vasoproliferative factors that induce formation of new blood vessels in the retina or iris. This stage of the disease is called proliferative diabetic retinopathy (PDR). The proliferative retinal response is thought to be initiated by decreased oxygen levels as a result of retinal capillary nonperfusion.^{23,24} Retinal neovascularization occurs commonly at the borders of perfused and nonperfused retina and is more common and severe in eyes with extensive nonperfusion. Retinal neovascularization also occurs commonly at the optic nerve head (Fig. 40-3) and along the temporal vascular arcades. The new vessels grow along the surface of the retina and along the vitreous scaffold of the posterior vitreous hyaloid. The new vessels are fragile and commonly bleed, resulting in preretinal and vitreous hemorrhage (Fig. 40-4). In addition, glial tissue associated with these new vessels can contract and result in traction on the retina, eventually leading to retinal detachment (Figs. 40-5 and 40-6). Vitreous hemorrhage and traction retinal detachment are responsible for most cases of severe visual loss from diabetic retinopathy.⁵

Macular edema is another important component of diabetic retinopathy. Diabetes causes an increase in retinal vascular permeability. Vessel leakage can occur at any stage of diabetic retinopathy, resulting in edema and thickening of the retina. When present in the macular area of the retina, this thickening is called macular edema. Macular edema is a common cause of moderate visual loss in patients with diabetes⁵ and accounts for the majority of all visual loss in patients with DM.

BIOCHEMICAL MECHANISMS UNDERLYING NONPROLIFERATIVE DIABETIC RETINOPATHY

Several biochemical mechanisms have been proposed to explain the adverse systemic effects of hyperglycemia.^{25,26} Extracellular glucose has been shown to react nonenzymatically with primary amines of proteins to form intermediate glycation products.^{27,28} These intermediate products can further react to form advanced

FIGURE 40-1. Trypsin digest preparation of retina from a patient with non-proliferative diabetic retinopathy showing scarcity of pericytes, with small, dark nuclei (arrow), relative to endothelial cells; a capillary microaneurysm (center); and acellular capillaries (arrowheads) (original magnification $\times 160$).

FIGURE 40-2. Retinal nerve fiber layer infarction (cotton-wool spot), showing distended nerve axons (cytoid bodies) (arrows). GCL, ganglion cell layer; INL, inner nuclear layer; ONL, outer nuclear layer (hematoxylin & eosin, original magnification $\times 40$).

FIGURE 40-6. Retinal detachment. Area where vitreous band (arrow) is attached to tented-up retina in eye with proliferative diabetic retinopathy with traction retinal detachment (hematoxylin & eosin, original magnification $\times 100$).

glycation end-products (AGEs). Infusion of AGEs in animals can mimic some of the vascular abnormalities observed in diabetes, particularly basement membrane thickening and changes in vascular contractility.⁵ Studies investigating inhibitors of AGE formation, such as aminoguanidine, have demonstrated a reduction in basement membrane thickening and early changes in the retinal vasculature in diabetic rats.^{27,29,30}

Excessive extracellular glucose may be transported inside the cell by glucose transporters, where it is metabolized, resulting in a change of redox potential. The resulting increase in oxidative stress has been postulated to be a fundamental factor underlying the biochemical changes associated with complications of diabetes, including diabetic retinopathy. Studies involving antioxidants have demonstrated ameliorative effects on various functions, including normalization of retinal blood flow in human patients with diabetes.³¹ Whether antioxidants can be utilized as a therapy to prevent subsequent complications of diabetic retinopathy remains to be determined by prospective clinical trials. Influx of glucose also leads to the production of sorbitol by means of the aldose reductase pathway. Excessive sorbitol production has been postulated to be involved in cataract formation in diabetes.³² However, a major role for sorbitol in diabetic retinopathy is less likely, since studies to date of aldose reductase inhibitors indicate that they have not prevented retinopathy in diabetic and galactosemic dogs; in addition, such inhibitors have not prevented or delayed the progression of diabetic retinopathy in human clinical trials.³³

PROTEIN KINASE C AND ITS ROLE IN DIABETIC RETINOPATHY

Hyperglycemia-Induced PKC Activation

The activation of PKC by hyperglycemia and diabetes is related to increases in intracellular diacylglycerol (DAG) levels, the physiologic activator of PKC. In diabetic animal models, DAG levels have been found to be elevated in various tissues, including retina,³⁴ aorta, heart,³⁵ renal glomeruli,^{36,37} and liver.³⁸ This elevation in DAG levels appears to be chronic. In diabetic dogs, for instance, DAG levels remain increased even after 5 years of disease.³⁹ The effect of elevated glucose levels in increasing DAG levels has been confirmed using cultured vascular cells, including retinal endothelial cells.³⁴

Although cellular DAG can be increased through several mechanisms, most studies indicate that hyperglycemia-induced DAG results from *de novo* synthesis.^{25,26} In this pathway, glucose-6-phosphate is metabolized through glycolysis to generate glyceraldehyde-3-phosphate, which in turn is further metabolized to generate phosphatidic acid and DAG. This *de novo* synthesis of DAG production generates DAG containing both saturated and unsaturated fatty acids, which is capable of activating PKC.

Accordingly, the increase in DAG levels is accompanied by PKC activation in diabetes mellitus as demonstrated in retina,³⁴ aorta, heart,³⁵ and renal glomeruli.³⁷ Increased PKC activity has also been observed in cultured cells, including retinal endothelial cells.³⁴ Diabetes and high glucose levels activate specific PKC isoforms. PKC- β_2 is activated predominantly in the aorta and heart of diabetic rats.³⁵ PKC- α , - β_1 , - β_2 , and - ϵ are activated in the retina of diabetic rats,³⁴ although PKC- β isoforms show a greater increase than do the others.

Multiple vascular alterations in the retina have been attributed to the activation of DAG and PKC. These include changes in vas-

cular blood flow, capillary basement membrane thickening, vascular permeability, and neovascularization. Retinal blood flow is decreased in animals and patients with short-duration diabetes. Several observations support the role of PKC activation in decreasing retinal blood flow. Intravitreal injection of a PKC agonist, such as phorbol ester, decreases retinal blood flow.³⁴ Conversely, decreases in retinal blood flow observed in diabetic animals and patients are normalized by PKC inhibitors.^{34,36}

Capillary basement membrane thickening is a classical structural change in diabetes, and is present in many tissues including retina, renal glomeruli, heart, and muscle.⁶ Aside from providing structural support, the capillary basement membrane is involved in regulating vascular permeability, cell adhesion, proliferation, differentiation, and gene expression. Alterations in basement membrane composition could therefore result in vascular dysfunction.

Most studies of capillary basement membrane changes in diabetes have focused on the renal glomeruli. Histologic studies have demonstrated increases in type IV and VI collagen, fibronectin, and laminin, and decreases in proteoglycans in the mesangium of patients with diabetic nephropathy.^{40,41} These changes are also found in cultured mesangial cells incubated in high glucose and were prevented by general PKC inhibitors.^{42–47}

Increased vascular permeability is a classic characteristic of diabetic retinopathy. In the retina, vascular leakage can be detected at sites of microaneurysms and retinal exudates (Fig. 40-7). Increased retinal vascular permeability presumably leads to the development of macular edema, which is the leading cause of moderate visual loss from diabetes. In diabetic animals, increased retinal vascular permeability to albumin can occur after only 4–6 weeks of chemically induced diabetes.⁴⁸ PKC activation increases the permeability of cultured endothelial cells to albumin and other macromolecules.^{49,50}

PKC activation could also increase vascular permeability by its action on growth factors such as vascular endothelial growth factor (VEGF) (see below). VEGF increases in the diabetic retina before extensive retinal ischemia or neovascularization occurs.^{51,52} Thus it could play a role in increasing retinal vascular permeability in nonproliferative diabetic retinopathy. In aortic smooth muscle, elevated glucose concentrations increase PKC activation and VEGF expression. This effect is inhibited by PKC inhibitors.⁵³ Furthermore, intravitreal injection of VEGF activates protein kinase C and increases retinal vascular permeability in rats. Of

FIGURE 40-7. Hard exudates (asterisks) in the outer plexiform layer of the macula in a patient with nonproliferative diabetic retinopathy. GCL, ganglion cell layer; INL, inner nuclear layer; ONL, outer nuclear layer (hematoxylin & eosin, original magnification $\times 100$).

potential therapeutic importance, VEGF-induced permeability is almost completely inhibited by oral administration of a PKC- β selective inhibitor.⁵⁴

Therapeutic Potential for PKC- β Inhibition

From the preceding discussion it is evident that PKC inhibitors may prove therapeutically useful in preventing or delaying ocular complications of DM. Indeed, in diabetic rats, abnormal retinal and renal hemodynamics and increases in albuminuria were normalized by oral administration of a PKC- β isoform selective inhibitor, LY333531. LY333531 inhibited diabetes-induced PKC activation in the retina and renal glomeruli.³⁶ In addition, LY333531 prevented the overexpression of TGF- β , type IV collagen, and fibronectin in the renal glomeruli of diabetic rats.⁵⁵ These studies strongly suggest a role for the PKC- β isoform in mediating diabetic vascular complications in the retina and kidney. As discussed below, inhibition of PKC- β has been shown to prevent growth factor-induced retinal vascular permeability and to normalize diabetes-induced changes in retinal blood flow, further suggesting its potential therapeutic usefulness.

THE ROLE OF GROWTH FACTORS IN PROLIFERATIVE DIABETIC RETINOPATHY

Retinal neovascularization is the principal cause of severe visual loss in patients with diabetes (Fig. 40-8). Neovascularization associated with ischemic retinopathies (such as diabetic retinopathy) is commonly preceded by retinal capillary nonperfusion^{56,57} and frequently arises at the border of perfused and nonperfused areas of the retina. Neovascularization is more common and severe in eyes with more extensive retinal capillary nonperfusion.⁵⁸ These observations suggest that an angiogenic factor, released by ischemic/hypoxic retina may be responsible for stimulating new blood vessel growth in diabetic retinopathy. This theory was first proposed by Michaelson in 1948²³ and later refined by Ashton and others.

Several growth factors have been evaluated for their potential involvement in stimulating retinal neovascularization.⁵⁹ Most notably, these include fibroblast growth factor-2 (FGF-2), growth hor-

mone, and the insulin-like growth factors. More recently, vascular endothelial growth factor (VEGF) has emerged as a principal mediator of neovascularization in diabetic retinopathy.

VASCULAR ENDOTHELIAL GROWTH FACTOR

Vascular endothelial growth factor (VEGF), also known as vasopermeability factor (VPF), is a glycoprotein with both vasopermeability^{60,61} and angiogenic activity.^{62,63} VEGF is primarily mitogenic for endothelial cells.^{64,65} Its expression has been found to be significantly increased in rapidly growing, highly vascularized tumors.⁶⁶ Furthermore, hypoxia induces VEGF expression in tumors and glial myogenic tumor cell lines.⁶⁷ VEGF binds several high-affinity cell surface tyrosine kinase receptors, the best characterized being fms-like tyrosine kinase (Flt) and fetal liver kinase 1 (Flk-1). VEGF and its receptors are critical for normal embryologic development, since even heterozygous knockout of these genes results in lethal disruption of the macro- and microvasculature.^{68,69} These characteristics suggested that VEGF may play a major role in mediating the microvascular complications observed in diabetic retinopathy, which are characterized by tissue ischemia, angiogenesis, and vascular permeability. Indeed, numerous investigations of VEGF in ocular cells, animal models, and patients have implicated VEGF in the etiology of diabetic retinopathy.

Many cell types within the eye produce VEGF, including retinal pigment epithelial cells, pericytes, endothelial cells, glial cells, Müller cells, and ganglion cells.^{70,71} Furthermore, hypoxia induces VEGF mRNA expression in various ocular cell cultures.⁷¹ This mRNA induction is reversible following return of the cells to a normoxic environment. Retinal microvascular endothelial cells express high-affinity VEGF receptors on their cell surface at a higher density than many other endothelial cell types.⁷² VEGF is capable of stimulating retinal endothelial cell growth in culture.

Investigations of animal models of ischemic retinopathy lend further support to VEGF's underlying role in ocular neovascularization. When neonatal mice,⁷³ rats,⁷⁴ or cats⁷⁵ are exposed to elevated concentrations of oxygen at specific times after birth, incomplete vascularization of the retina results. When the animals are returned to room air, the retinas become relatively hypoxic because of the experimentally induced retinal capillary nonperfusion. Neovascularization of the retina and the optic disc subsequently occurs. This neovascularization is clinically and histologically similar to that observed in humans with ischemic retinopathies such as diabetic retinopathy. In the mouse model, VEGF mRNA levels increase over threefold within 12 hours of relative retinal hypoxia and are maintained for many days thereafter, slowly declining as clinically apparent neovascularization regresses.⁷⁶ VEGF expression in this model is particularly prominent just anterior to regions of retinal neovascularization. Similar findings have been observed in the rat⁷⁴ and cat^{75,77} models as well. VEGF mRNA and protein levels also correlate with the development of iris neovascularization in a monkey model of experimentally induced retinal vein occlusion.⁷⁸ These models all demonstrate a temporal relationship of increased VEGF expression observed after the onset of retinal hypoxia, but before the development of new vessels.

Clinical Studies

Support for the role of VEGF as a mediator of diabetic retinal neovascularization has been found in clinical studies evaluating the

FIGURE 40-8. Early retinal neovascularization, with a new vessel (arrow) extending into the vitreous from the retina (hematoxylin & eosin, original magnification $\times 160$).

correlation between proliferative retinopathies (including diabetic retinopathy) and intraocular VEGF concentrations. In one study,⁷⁹ ocular fluid specimens were obtained from 164 patients undergoing intraocular surgery, including 31 patients without neovascular disorders and 143 patients with diabetes. Patients in the latter group had different stages of retinopathy, including no retinopathy, nonproliferative retinopathy, quiescent proliferative retinopathy, and active proliferative retinopathy. VEGF concentrations were found to be markedly elevated in both the vitreous and aqueous of patients with active proliferative retinopathy. In contrast, VEGF levels were low in control patients as well as in diabetic patients with no retinopathy, nonproliferative retinopathy, or quiescent proliferative retinopathy. In six patients who underwent successful laser photocoagulation treatment of active proliferative retinopathy, intraocular VEGF levels after treatment were reduced by an average of 75% compared to before treatment. Similar findings were observed in another study⁸⁰ measuring vitreous VEGF concentrations in 8 patients with proliferative diabetic retinopathy as compared to 12 patients who underwent vitrectomy for disorders without associated neovascularization. These findings have now been confirmed by numerous studies.^{81–86}

Inhibition of VEGF- and Retinopathy-Associated Complications

The establishment of a causal relationship for VEGF in ocular neovascularization has been provided by VEGF inhibition studies in animal models. VEGF inhibitory molecules evaluated in animals include VEGF receptor chimeric proteins, neutralizing antibodies, and antisense phosphorothioate oligodeoxynucleotides.

VEGF receptor chimeric proteins were constructed by joining the extracellular domain of the Flt receptor or the Flk-1 receptor with the heavy chain of IgG.⁸⁷ These molecules bind VEGF with the same affinity as native receptors and can therefore act as competitors for VEGF binding. Injection of these chimeric proteins into the mouse model of retinal neovascularization discussed above was performed just when the retinas became hypoxic. Single or dual injections of either chimeric protein significantly reduced retinal neovascularization, with a mean suppression of approximately 50%.⁸⁸

Antisense phosphorothioate oligodeoxynucleotides have been studied in the same model. Two different VEGF antisense molecules were found to reduce VEGF protein levels by 40–66%, while decreasing new blood vessel growth by 25% and 31% as compared to sense or noncomplementary mRNA controls.⁸⁹ VEGF neutralizing antibodies have been studied in the primate model of iris neovascularization. Intravitreal injections administered every other day for 2 weeks resulted in inhibition of iris neovascularization as assessed by fluorescein iris angiograms.⁹⁰

These studies suggest that VEGF mediates ocular neovascularization in general and proliferative diabetic retinopathy in particular. For advanced diabetic eye disease, the potential therapeutic implications of modulating these pathways is obvious and the focus of substantial current research efforts.

VEGF and Nonproliferative Diabetic Retinopathy and Macular Edema

Interestingly, recent findings suggest a potential role for VEGF in nonproliferative diabetic retinopathy as well. Increased levels of VEGF were found in a study of postmortem eyes of patients with nonproliferative diabetic retinopathy as compared with nondiabetic

controls.⁵¹ In addition, repeated injections of VEGF at high concentrations into primate eyes produced retinal changes resembling nonproliferative diabetic retinopathy, including blood vessel tortuosity, venous beading, capillary abnormalities resembling microaneurysms, intraretinal hemorrhages, capillary closure, and increases in vascular permeability.⁹¹

VEGF may also play an important role in the pathogenesis of diabetic macular edema, a condition resulting from excessive permeability of retinal vessels in patients with diabetes (Fig. 40-9). In the dermal microvasculature, VEGF is 50,000 times more potent than histamine in producing vasopermeability.⁶¹ VEGF efficiently increases retinal vascular permeability as well.^{54,92} The mechanism underlying this response may be related to VEGF downregulation of the interendothelial tight junction protein occludin, and/or to VEGF-induced phosphorylation of the tight junction proteins occludin and zonula occludin 1. Both of these responses have been demonstrated to occur in cultured retinal endothelial cells.^{93,94} Since VEGF is increased in the diabetic retina before extensive retinal ischemia or neovascularization occurs,^{51,52} it could account for diabetic macular edema that may occur at any stage of diabetic retinopathy.

As discussed above, VEGF-induced increases in vascular permeability in rats can be inhibited by oral administration of a PKC β selective inhibitor. The mitogenic effects of VEGF on cultured vascular endothelial cells can also be significantly reduced by PKC- β inhibition.⁹⁵ Protein kinase C activation therefore appears to also play an important role in diabetic retinal vascular complications through mediating the effect of VEGF.

GROWTH HORMONE AND INSULIN-LIKE GROWTH FACTORS

The role for growth hormone (GH) and its downstream mediators such as insulin-like growth factor-1 (IGF-1) in the pathogenesis of diabetic retinal neovascularization has been extensively evaluated. Based on the observation of regressing proliferative diabetic retinopathy (PDR) after infarction of the pituitary following pregnancy (Sheehan's syndrome) and partial responses of PDR following pituitary ablation, the role of GH/IGF-1 has been sought.^{96–98} However, conditions in which GH is elevated (e.g., acromegaly) are not necessarily associated with retinal neovascularization.^{99,100}

FIGURE 40-9. Diabetic macular edema, with the accumulation of a light-staining proteinaceous material in the outer plexiform (asterisks) and inner nuclear (arrows) layers of the retina. GCL, ganglion cell layer; INL, inner nuclear layer; ONL, outer nuclear layer (hematoxylin & eosin, original magnification $\times 100$).

In addition, studies of vitreous and serum levels of IGF-I have not consistently demonstrated a correlation with retinal neovascularization, in contrast to VEGF.¹⁰¹⁻¹⁰³

Although the involvement of GH and IGF-I in initiating diabetic retinal neovascularization may be limited, evidence suggests that they may play a key permissive role in the neovascular process. Studies using the mouse model of retinopathy described above demonstrate this point. Retinal neovascularization was found to be reduced by up to 44% in these mice after systemic administration of an inhibitor of GH secretion, as compared to control animals; similar results were found in transgenic mice expressing a GH antagonist gene. The inhibition was reversed by exogenous IGF-I administration. Interestingly, a transgenic mouse expressing a GH agonist that results in a giant phenotype did not exhibit an increase in neovascularization.¹⁰⁴

Another study demonstrated that administration of an IGF-I receptor antagonist suppressed retinal neovascularization in the mouse model by up to 53%. In addition, this IGF-I receptor antagonist reduced VEGF activation of the mitogen-activated protein kinase (MAPK) signaling cascade.¹⁰⁵ Taken together, these studies suggest that IGF-I plays a role in creating a permissive environment for the stimulation of retinal neovascularization by VEGF.

INHIBITORS OF NEOVASCULARIZATION

Recently, attention has been focused on the possible role of endogenous angiogenic inhibitors such as pigment epithelium-derived factor (PEDF) in the eye. PEDF was first isolated from retinal pigment epithelial cells and has been actively studied as a neurotrophic factor.^{106,107} It was recently found to potently inhibit corneal neovascularization in a mouse model.¹⁰⁸ PEDF blocks VEGF action *in vitro* in cultured endothelial cell migration assays. Temporal expression of PEDF in the mouse retina was found to be closely correlated with blood vessel maturation.

PEDF has been found to be present in the cornea and vitreous, two avascular areas of the eye. The ability of corneal extracts and vitreous specimens to inhibit neovascularization was neutralized by antibodies to PEDF. Finally, PEDF was found to be downregulated by hypoxia in a retinoblastoma cell line.¹⁰⁸ This last observation has particularly interesting implications for proliferative diabetic retinopathy. It is possible that ischemia/hypoxia resulting from diabetic microvascular disease may downregulate PEDF, thereby allowing growth factors such as VEGF to stimulate neovascularization.¹⁰⁹

Transforming growth factor-beta (TGF- β) is another soluble factor that may inhibit blood vessel growth in the eye. The pericyte loss that characterizes early diabetic retinopathy has led to speculation that pericytes may play an inhibitory role in retinal capillary growth.¹¹⁰ Coculturing capillary endothelial cells and pericytes results in inhibition of endothelial cell proliferation; this inhibition is mediated by TGF- β , which is activated on contact between the cells.¹¹

It is probable that other inhibitory factors are also involved in retinal blood vessel regulation. Current views on the pathobiology underlying diabetic retinopathy is that the proliferative complications arise after the relative angiogenic and antiangiogenic balance is tipped in favor of angiogenesis, either by enhancing growth stimuli or reducing antigrowth stimuli. The therapeutic implications of antagonizing angiogenic activity and/or augmenting antiangiogenic activity are currently under investigation.

NEOVASCULAR GLAUCOMA

A particularly destructive complication of proliferative diabetic retinopathy is neovascular glaucoma. In addition to retinal neovascularization, angiogenesis can involve the anterior portion of the eye, including the iris (rubeosis iridis) and the anterior chamber angle (Fig. 40-10). Neovascularization of the angle can obstruct aqueous fluid outflow, resulting in neovascular glaucoma, a severe sight-threatening disorder. As with retinal neovascularization, VEGF is thought to be a major stimulus for neovascularization of the iris and angle. VEGF levels correlate with the development of iris neovascularization in a monkey model of laser-induced retinal vein occlusion.⁷⁸ Intravitreal injections of VEGF in primates were sufficient to induce iris neovascularization,¹¹¹ while intravitreal injections of antibody against VEGF resulted in inhibition of iris neovascularization. Finally, intraocular concentrations of VEGF are elevated in the eyes of patients with rubeosis iridis.⁷⁹

DIABETIC CATARACT FORMATION

Cataracts are a common cause of visual impairment in patients with diabetes. Two types of cataract are observed in diabetes.^{112,113} The true diabetic cataract, or snowflake cataract, occurs in young adults, children, and even infants with severe hyperglycemia. This type of cataract is rarely encountered in the United States today. The senescent cataract is clinically similar to that seen in the normal population, although evidence suggests that patients with diabetes are at increased risk and often develop this type of cataract at a younger age.

The sorbitol-polyol pathway has classically been implicated in cataract formation in diabetes. It has been demonstrated in most cells exposed to high glucose concentrations that glucose can be converted to sorbitol by the enzyme aldose reductase.¹¹⁴ Although sorbitol can be metabolized into fructose by sorbitol dehydrogenase, this reaction occurs slowly, resulting in cellular accumulation of sorbitol, since sorbitol does not diffuse across cell membranes.¹¹⁴ Cellular damage could occur as a result of osmotic stress, with influx of water leading to swelling of lens fiber cells. In support of this hypothesis, polyols have been observed to accumu-

FIGURE 40-10. Eye with proliferative diabetic retinopathy, iris neovascularization (arrow), and closure of the anterior chamber angle by peripheral anterior synechiae (asterisk) (hematoxylin & eosin, original magnification $\times 40$).

late in the lenses of diabetic animals.^{32,115} However, the role of polyols in diabetic cataract formation in humans is less clear. Although sorbitol levels are increased in proportion to the level of hyperglycemia in the lenses of adults with diabetes, these levels may not be high enough to result in significant osmotic effects.¹¹⁶

A second mechanism for cataract formation in diabetes is nonenzymatic glycation of lens proteins such as the crystallins. The crystallins represent about 86% of the total lens proteins. Aggregation of these proteins occurs gradually as a normal consequence of aging; the aggregates thus formed lose their ability to transmit light. Diabetes is thought to accelerate nonenzymatic glycation of crystallins, increasing their susceptibility to oxidative damage, which leads to covalent cross-linking of the crystallins via disulfide bonds.¹¹⁷ An increase in the glycation rate has been observed, particularly in alpha-crystallins.¹¹⁸ In diabetic rats, glycation of lens proteins increased with time after induction of diabetes and was accompanied by an increase in high-molecular-weight aggregates.¹¹⁹ Increased glycation of crystallins has also been observed in human diabetic cataracts,^{120,121} suggesting that this mechanism may play a role in the pathogenesis of diabetic cataract formation in humans.

CONCLUSIONS

Diabetic retinopathy is a significant cause of morbidity throughout the world, accounting for the majority of severe visual loss among working-age adults in developed countries. Recent discoveries have provided significant insight into the growth factors and signal transduction mechanisms underlying this disease. As a result, we now have a more detailed understanding of the pathobiology of diabetic retinopathy. This knowledge has provided new therapeutic targets currently under investigation. Such studies hold the promise for a possible new age of pharmacologic therapies for the complications of diabetes in the eye.

Acknowledgments. The authors express their thanks to Dr. W. Richard Green, Ocular Pathologist at the Wilmer Eye Institute, Johns Hopkins Hospital, for providing all of the histopathologic photos in this chapter.

Disclosure

The epidemiology, natural history, and clinical findings of diabetic retinopathy have frequently been presented. In addition, the potential roles of growth factors and underlying mechanisms of diabetic retinopathy have been reviewed extensively in recent years. The reports of fundamental studies and comprehensive reviews of their results are widely quoted and paraphrased. In order to maintain consistent descriptive accuracy of many of these fundamentals, portions of this chapter have been derived from prior publications, including Aiello and colleagues⁵ and Aiello.⁵⁹

Retinopathy and Other Ocular Complications in Diabetes

Ronald Klein

Diabetic retinopathy is an important cause of visual impairment in the United States.¹ While its natural history has been described, its pathogenesis is not known.² Available data suggest that good glycemic and blood pressure control reduces the risk of the development and progression of retinopathy.³⁻⁶ Early identification and treatment of proliferative retinopathy or macular edema with photocoagulation may prevent or delay the development of visual loss.^{7,8} This chapter describes current concepts about the natural history, pathogenesis, diagnosis, and management of retinopathy as well as other ocular complications of diabetes that may result in visual loss.

DIABETIC RETINOPATHY

Retinal Anatomy

The retina is a thin, transparent neural tissue lining the inner part of the eye.⁹ It is in contact with the clear vitreous gel internally and the choroid externally. The retina varies in thickness from 0.1 mm at the fovea and far periphery to 0.55 mm at the macula. There are ten well-defined retinal layers consisting of the nuclei of three sequential neurons, their axons and synaptic connections, and glial supporting cells with little extracellular space. A central retinal artery derived from the ophthalmic artery branches into arterioles at the optic nerve head and supplies blood to the internal two thirds of the retina; the choriocapillaris of the choroid supplies nutrition to the external one third. A blood-retinal barrier comprised of tight junctions of the endothelial cells of the retinal blood vessels and the retinal pigment epithelial cells prevents penetration of all but a few important metabolic products into the retina.

The macular area measures approximately 4 mm in diameter and is centered 4 mm temporal to the optic disk. The fovea, a depression in the inner retinal surface of the macula, is 1.5 mm in diameter (Fig. 41-1). A retinal capillary-free zone of 450–600 μm exists in its center, where the retinal tissue is fed by the choriocapillaris of the choroidal circulation. The central portion of the fovea (or foveola) contains only cone photoreceptors, which are important for the best visual acuity (finest spatial resolution) and highest quality trichromatic color vision.

Natural History

The earliest clinically apparent manifestations of diabetic retinopathy are classified as nonproliferative. During this phase a number of pathophysiologic changes associated with diabetes occur in the

microvasculature; these include occlusion, dilation, and increase permeability of the small retinal blood vessels.^{10,11} Histologic changes that occur prior to the appearance of retinopathy, early in the course of the disease, are degeneration of retinal capillary pericytes (mural cells) and thickening of the capillary basement membrane.^{10,11}

Usually the first changes seen with the ophthalmoscope are retinal microaneurysms, small outpouchings of the retinal capillaries (Fig. 41-1). They appear as small circular red dots, varying in size from about 20–200 μm . Retinal microaneurysms typically arise in areas of capillary closure. These lesions demonstrate at normal permeability of the endothelial cell wall to fluorescein and possibly to lipoproteins. With time, the walls may thicken with deposition of periodic acid-Schiff (PAS)-positive and lipid material and stagnant blood may be trapped in the lumen. If there is further thickening of the wall and obliteration of the lumen, the microaneurysm may then appear yellow or white on clinical examination. Occlusion of the feeding capillary or complete hyalinization of the lumen may be responsible for the microaneurysm's ultimate disappearance.¹¹ Microaneurysms have been reported to have variable survival rates, and their average disappearance rate has been estimated at 3.3%/month.¹²

The number of retinal microaneurysms in an eye is an important predictor of progression of diabetic retinopathy.¹³ In the Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR), there was an increased risk of progression of diabetic retinopathy over 4-year period when four or more retinal microaneurysms were present at baseline. Furthermore, the increase in the number of retinal microaneurysms and the ratio of the number of retinal microaneurysms at the 4-year follow-up to the number at baseline were positively associated with the incidence of proliferative retinopathy or clinically significant macular edema at the 10-year WESDR follow-up.¹⁴ Baudoin and coworkers¹⁵ developed a standardized reproducible method for quantitating the number of retinal microaneurysms using fluorescein angiograms. Microaneurysm count are useful for study of the early natural history of diabetic retinopathy and as an end point in clinical trials to evaluate the effects of treatment or intervention. Retinal microaneurysms generally do not make their appearance until at least 3 years after diagnosis of diabetes.^{16,17} They are found in about 69% of people with a history of 10 years of type 1 diabetes mellitus (T1DM).¹⁶ In adults with type 2 diabetes mellitus (T2DM), retinal microaneurysms are present in 55% of the population who have had diabetes for 10 years.¹⁷ Retinal microaneurysms can occur in nondiabetic patients with other conditions associated with retinal ischemia, for example, branch

FIGURE 41-1. Fundus photograph of right eye. The foveal area (F) corresponds approximately to the dark central portion of the photograph. A retinal microaneurysm (**black arrow**) appears as a small dark spot with sharp margins and retinal hard exudates appear as white deposits with sharp margins just nasal to the foveal area (**white arrowhead**). The visual acuity in this eye is 20/15.

retinal vein occlusion, carotid artery disease, AIDS, and hypertensive retinopathy. Single retinal microaneurysms were found in 3.7% and multiple microaneurysms in 1.2% of eyes in a nondiabetic population.¹⁸ Because hypertension and carotid artery disease are not uncommon in older-onset diabetic people, it may be difficult to determine whether diabetes or the presence of other systemic diseases is the cause of the microaneurysms when they are the only sign of retinopathy in the eyes of older-onset diabetic people.

Retinal microaneurysms by themselves are usually not a threat to vision. However, as the disease progresses, retinal blot hemorrhages and hard exudates appear. Retinal blot hemorrhages are round with blurred edges and result from an extravasation of blood

from retinal capillaries or microaneurysms into the inner nuclear layer of the retina (Fig. 41-2). They are not fluorescent on angiography and usually disappear within 3–4 months.

Retinal hard exudates are variable in size, sharply defined, and yellow; they may be scattered, aggregated, or ring-like in their distributions (Figs. 41-1 and 41-2). Hard exudates result from leakage of lipoprotein material from retinal capillaries or microaneurysms into the outer retinal layer; and they may last from months to years.¹⁹ The exudate forms preferentially in the posterior retina, especially temporal to the macula, and may extend into the macula, reducing visual acuity. On ophthalmoscopy, retinal hard exudates are sometimes confused with drusen, which are deposits of PAS-positive material located between the retinal pigment epithelium and Bruch's membrane. Drusen are not characteristic of diabetes, but occur frequently in older individuals. Differentiation between hard exudates and drusen may be difficult in some cases if the examination is done using the direct ophthalmoscope, without stereopsis; drusen are usually rounder, more regular, and less yellow than hard exudates.

In the more advanced stages of nonproliferative retinopathy, closure of the retinal capillaries and arterioles occurs, causing decreased nutrition to the inner layers of the retina. These changes cause whitish or grayish swellings in the nerve fiber layer of the retina, termed "cotton-wool spots" or "soft exudates," which are infarcts of the nerve fiber layer (Figs. 41-2 to 41-4). They remain only a few weeks to months. After their disappearance, the retina may appear normal on ophthalmoscopy, but nonperfusion of retinal arterioles may be seen in fluorescein angiography. In some patients with severe ischemia, occlusion of larger arterioles results in larger areas of irreversible retinal nonperfusion, especially in the retinal midperiphery. Late in the course of the disease, severe ischemia with thin-sheathed sclerotic (white "thread-like") arterioles may appear.

Another manifestation of focal retinal ischemia is the presence of dilated capillaries (intraretinal microvascular abnormalities [IRMAs]) (Fig. 41-3). IRMAs are found in areas of capillary nonperfusion and may be abnormally permeable to plasma proteins;

FIGURE 41-2. Fundus photograph of the left eye showing various lesions associated with nonproliferative and proliferative diabetic retinopathy in an area superior and temporal to the macula. Retinal hard exudates (hex) appear as white deposits with sharp margins. Soft exudates (se) or cotton-wool spots appear as grayish white areas with ill-defined edges. Retinal blot hemorrhages appear as spots of varying size with irregular margins and uneven densities. Retinal new vessels (long black arrows) are present.

FIGURE 41-3. Fundus photograph of the left eye with preproliferative retinopathy. Soft exudates or cotton-wool spots appear as grayish white areas with ill-defined edges (**small thick white arrows**); intraretinal microvascular abnormalities (**thin white arrow**), venous dilation, and retinal hemorrhages are present. (Reprinted with permission from Klein R: *Retinopathy and other ocular complications in diabetes*. In: Olefsky JM, Sherwin R, eds. *Diabetes Mellitus: Management and Complications*. Churchill Livingstone: 1985;101.)

they are considered by some to be a compensatory response to hypoxia.¹¹ Venous beading, duplication, and kinks also occur in response to hypoxia in areas of focal ischemia (Fig. 41-4). These kinks or loops in eyes with diabetic retinopathy are thought to be shunt vessels developed to bypass a nonthrombotic occlusion of larger retinal veins.²⁰ Many large, dark intraretinal hemorrhages may also appear secondary to retinal ischemia and are thought to represent hemorrhagic infarcts (Fig. 41-4).¹⁰

FIGURE 41-4. Fundus photograph of the left eye. Retinal venous dilation and beading (**black arrows**) and an area of reduplication are present (**large white arrow**). Slow flow is manifested by "boxcaring" in the small retinal branch vein (**small white arrow**). Intraretinal microvascular abnormalities and a cotton-wool spot (**cw**) are present in this very ischemic retina. (Reprinted with permission from Klein R: *Retinopathy and other ocular complications in diabetes*. In: Olefsky JM, Sherwin R, eds. *Diabetes Mellitus: Management and Complications*. Churchill Livingstone: 1985;101.)

The presence of cotton-wool spots, venous irregularities, IRMAs, and dark intraretinal hemorrhages constitutes what has been called the "preproliferative phase"; eyes with these changes have a significantly increased risk of developing proliferative retinopathy.¹⁰ In the Early Treatment Diabetic Retinopathy Study (ETDRS), eyes with multiple areas of venous beading, severe IRMAs, and large areas of intraretinal hemorrhages (ETDRS Level 55) had a 55% rate of progression to proliferative retinopathy over a 1-year interval.²¹ Therefore the appearance of these lesions is considered a warning sign of impending growth of new retinal vessels.

Proliferative diabetic retinopathy is characterized by growth of abnormal blood vessels and fibrous tissue from the optic nerve head (Fig. 41-5) or from the inner retinal surface (usually near or from retinal veins) (Fig. 41-6). The vessels, which appear initially as fine tufts on the surface of the retina, subsequently grow into the outermost layer of the vitreous. Initially they consist of fine "naked"

FIGURE 41-5. Fundus photograph of the right eye. This sequence of photographs demonstrated progression from early proliferative retinopathy manifested initially as fine tufts of retinal new vessels on the optic disk (**A**, dated 2/75) (**black arrows**). There was further growth of retinal new vessels (**B**, dated 4/76) (**black arrows**). (Reprinted with permission from Klein R: *Retinopathy and other ocular complications in diabetes*. In: Olefsky JM, Sherwin R, eds. *Diabetes Mellitus: Management and Complications*. Churchill Livingstone: 1985;101.)

FIGURE 41-6. Fundus photograph of the left eye showing progression from nonproliferative to proliferative diabetic retinopathy in an area superior and temporal to the macula. **A.** When the patient was seen in 11/72 she was 25 years old and had a 14-year history of type 1 diabetic retinopathy. A few dilated capillaries and retinal microaneurysms are present here, and cotton-wool spots and blot hemorrhages were present in the macular area (not in photograph). The visual acuity was 20/15. **B.** In 3/76, flat retinal new vessels (**small black arrows**) are present. An abrupt termination of a branch arteriole (**black arrowhead**), intraretinal microvascular abnormalities (**white arrow**), and venous beading are present. **C.** By 10/76, there is an increase in the size of the retinal new vessels (**black arrows**) and the "feeder" vessel from the vein. The small arterioles above the vein are sheathed and appear white (**small black arrowheads**). **D.** This picture was taken in 2/77, 2 hours after laser treatment: the photocoagulation burns appear white (**b**). A small preretinal hemorrhage, appearing black, is present (**white arrowhead**).

FIGURE 41-6 (continued) E, F. In 6/77 the visual acuity was 20/30. An area of fibrovascular proliferation with traction on the retina superior and temporal to the macula was present (**white arrows**). G, H. On 7/15/77 further elevation of fibroproliferative tissue (**white arrows**) led to increased traction with detachment (**det**) of the area above the macula. The visual acuity had dropped to 20/70. I. The macular area became detached, and she underwent a vitrectomy and scleral buckle on 7/28/77. Corneal edema and blood in the anterior chamber developed after surgery. Later the eye became phthisical, and she had no light perception when this photograph was taken in 10/78. Her other eye had been enucleated in 4/77 as a result of pain from rubeotic glaucoma, secondary to traction retinal detachment and vitreous hemorrhage. (Courtesy of Dr. G. Bresnick, University of Wisconsin. Reprinted with permission from Klein R: *Retinopathy and other ocular complications in diabetes*. In: Olefsky JM, Sherwin R, eds. *Diabetes Mellitus: Management and Complications*. Churchill Livingstone:1985;101.)

vessels, which are permeable to fluorescein. These vessels may hemorrhage into the vitreous.

The mesenchymal cells responsible for the development of new blood vessels may also form fibrous tissue. Contraction of fibrovascular tissue may result in traction detachment of the retina. Fibrous tissue predominates and may remain as the only evidence of proliferative retinopathy if regression of new vessels occurs later in the course of the disease.

Diabetic Macular Disease

Occlusion or increased permeability of the retinal microvasculature that results in abnormal structure or function of the macular area has been called a primary or intraretinal maculopathy. Traction or dragging of the sensory retina due to shrinkage of fibrovascular vit-

reoretinal membranes causing altered macular function has been called secondary or vitreoretinal maculopathy.¹⁰

Increased permeability of retinal capillaries and retinal microaneurysms may result in accumulation of extracellular fluid and thickening of the normally compact retinal tissue. Initially, there may be a slight loss of the normal transparency of the retina and the edema may be easily missed by direct ophthalmoscopy. The leakage and resulting edema may be distributed around retinal microaneurysms or be diffuse and in some cases lead to the appearance of cystoid spaces in the outer retina. Focal leakage from retinal microaneurysms or capillaries is usually associated with the deposition of hard exudative material, in either small clumps, rings, or large deposits (Fig. 41-7). The rings of hard exudate usually surround edematous centers of leaking retinal vessels and microaneurysms, and they demarcate the border of nonedematous and

FIGURE 41-7. Fundus photographs of the macular area of the right eye demonstrating retinal hard exudates that appear as white deposits with sharp margins either scattered (**short thin black arrows**), ring-like (**short thick black arrows**), or aggregated in their distributions (**large black arrowheads**). Retinal blot hemorrhages (**white arrows**) and dark intraretinal hemorrhages (**large open black arrows**) are present. At the time photograph A was taken, the visual acuity was 20/15; 1 year later, when photograph B was taken, the visual acuity had dropped to 20/50. (Reprinted with permission from Klein R: *Retinopathy and other ocular complications in diabetes*. In: Olefsky JM, Sherwin R, eds. *Diabetes Mellitus: Management and Complications*. Churchill Livingstone: 1985;101.)

edematous retina. The accumulation of hard exudate in the macular area is usually gradual and may wax and wane, and spontaneous resolution of the exudate may occur in time.¹⁹

Macular edema appearing as diffuse thickening of the posterior retina is associated with retinal ischemia, and hard exudate is seldom present. The diffuse leakage of retinal blood vessels is a result of an extensive breakdown of the normally impermeable blood-retinal barrier of the capillary endothelial cells. Patients with diffuse edema have widespread extravasation of fluorescein dye from the capillaries to the retinal tissue during angiography. Based on the results of

the ETDRS,⁸ macular edema was defined as either being “clinically or not clinically significant.” In that study, clinically significant macular edema was associated with increased risk of loss of vision if left untreated with focal photocoagulation. Clinically significant macular edema was defined as the presence of either of the following: thickening of the retina located 500 μm or less from the center of the macula; or a zone of retinal thickening 1 disk area or larger in size, located within 1 disk diameter of the center of the macula.

Reduced oncotic pressure due to decreased serum albumin levels, increased intravascular fluid load, increased arteriolar perfu-

sion pressure, and tissue hypoxia has been postulated to cause macular edema by exacerbating breakdown of the blood–retinal barrier.²² Data from some studies suggest that high blood pressure, the presence of cardiovascular disease, and hyperlipidemia contribute to vascular occlusive disease in the retina with retinal ischemia and edema.²³ The presence of untreated diabetic renal failure has been thought to exacerbate the macular edema.²⁴ However, studies in patients with macular edema often fail to reveal a specific medical abnormality systematically associated with such edema.

Occlusion of small retinal vessels may result in enlargement of the normal 450- to 600- μ m diameter foveal avascular zone. This may result in decreased visual acuity in the absence of macular edema.¹⁰

The vitreoretinal maculopathies all involve traction on the macular area, vary in severity, and result from a number of processes. A grayish or translucent glistening epiretinal glial membrane may be seen on the inner retinal surface, and contraction of this membrane may lead to a wrinkling effect. These membranes are also found in older nondiabetic patients, in diabetic patients with nonproliferative disease, and after panretinal photocoagulation, but they are more common in patients with proliferative retinopathy.

In patients with proliferative retinopathy, shrinkage of fibrovascular tissue and detachment of the posterior vitreous surface may lead to an elevation or displacement of the sensory retina at the macula. A macular detachment may result from traction, leading to a retinal tear with fluid accumulation beneath the retina including the macular area, and a significant decrease in visual acuity.

Classification

Most clinicians, using direct ophthalmoscopy, will classify retinopathy as either absent or present, or as absent, nonproliferative retinopathy present, or proliferative stage present. However, for natural history, epidemiologic studies, and clinical trials, more sensitive and reproducible systems are necessary.

The modified Airlie House classification of diabetic retinopathy²⁵ and the ETDRS classification for severity of retinopathy based on the natural history of the disease, have been developed and used in a number of clinical and epidemiologic studies.^{4,7,8,11} These systems allow specification of the presence or absence of the severity of major lesions characteristic of diabetic retinopathy as well as the overall severity. One such severity scale is presented in Table 41-1. Data from the ETDRS demonstrated the validity of the scale. In that study, each stepwise increase in the severity level of retinopathy was associated with an increased risk of progression to proliferative retinopathy 4 years later.²¹ In addition, the WESDR, increasing severity of retinopathy as measured by the ETDRS severity scale at baseline was associated with increased risk of loss of vision over a 10-year follow-up.²⁷

The ETDRS severity scale places greater emphasis on moderate and more severe levels of diabetic retinopathy. Data from the WESDR suggest that microaneurysm counts from gradings of fundus photographs may provide a more sensitive measure of retinopathy severity in the earlier stages of disease.¹³ Photographic documentation of retinopathy and use of photographic standards for grading severity of retinal lesions allows detection of early changes, minimizes observer bias by masking the graders with respect to patient characteristics and treatments, provides monitoring of quality control of the documentation, and permits comparison over time. A number of studies have demonstrated that grading stereoscopic fundus photographs is more sensitive than ophthalmoscopy in detecting retinopathy.²⁸ Computer-assisted grading of digitized images has also been used to determine the presence and severity of diabetic retinopathy.^{29–32}

Pathogenesis

The exact pathogenesis of diabetic retinopathy is unknown (Chap. 40). It is assumed that retinopathy is a consequence of hyperglycemia. This is supported by (1) the strong association

TABLE 41-1. Modified Early Treatment Diabetic Retinopathy Severity Scale

Retinopathy	Level	Detailed Descriptor
None	Level 10	No retinopathy
Nonproliferative	Level 21	Microaneurysms (Ma) only or retinal hemorrhages (H) or soft exudates (Se) in the absence of microaneurysm
	Level 31	Microaneurysms plus one or more of the following: Venous loops $\geq 31 \mu$ m; questionable Se, intraretinal microvascular abnormalities (IRMA), or venous beading; and retinal hemorrhage
	Level 37	Microaneurysms plus one or more of the following: hard exudate (hex) and Se
	Level 43	Microaneurysms plus one or more of the following: H/Ma $\geq$ standard photo (SP) #1 in 4–5 fields; H/Ma $\geq$ SP #2A in 1 field; and IRMA in 1–3 fields
	Level 47	Microaneurysms plus one or more of the following: Both IRMA and H/Ma characteristics from level 43; IRMA in 4–5 fields; H/Ma $\geq$ SP #2A in 2–3 fields; and venous beading in 1 field
Preproliferative	Level 53	Microaneurysms plus one or more of the following: Any 2–3 of level 47 characteristics; H/Ma $\geq$ SP #2A in 4–5 fields; IRMA $\geq$ SP #8A; venous beading in 2 or more fields
Proliferative without DRS high-risk characteristics for severe visual loss (DRS-HRC)	Level 60	Fibrous proliferations only
	Level 61	No evidence of levels 60 or 65 but scars of photocoagulation either in “scatter” or confluent patches, presumably directed at new vessels
	Level 65	Proliferative diabetic retinopathy less than Diabetic Retinopathy Study high-risk characteristics (DRS-HRC). Lesions as follows: New vessels elsewhere (NVE); new vessels on or within 1 disk diameter (NVD) of the disk graded less than SP #10A; and preretinal (PRH) or vitreous hemorrhage (VH) < 1 disk area (DA)
Proliferative with DRS-HRC	Level 71	DRS-HRC, lesions as follows: VH and/or PRH ≥ 1 DA; NVE $\geq$ one-half DA with VH and/or PRH; NVD < SP #10A with VH and/or PRH; and NVD $\geq$ SP #10A
	Level 75	Advanced PDR, lesions as follows: NVD $\geq$ SP #10A with VH and/or PRH
Proliferative with DRS-HRC and loss of vision	Level 85	End stage PDR, lesions as follows: Macula obscured by VH and/or PRH; retinal detachment at center of macula; phthisis bulbi; and enucleation secondary to complications of diabetic retinopathy

retinopathy with increasing duration of disease;^{16,17} (2) the finding of retinopathy in secondary diabetes;³³ (3) the production of retinopathy in experimental diabetes in animal models;³⁴ and (4) the results of the epidemiologic studies and clinical trials that show a strong relationship of glycemia to the incidence and progression of retinopathy.^{3,4,35-41} However, the actual mechanism by which high blood glucose levels lead to retinopathy is not known.

There are several hypothesized but unproven pathogenetic explanations.^{10,11,42,43} One explanation is that hyperglycemia is an initiator of a number of biochemical changes, including an increase in aldose reductase activity, changes in myoinositol phosphatidylinositol metabolism, increases in 1,2-diacyl-sn-glycerol, nonenzymatic glycosylation, increased protein kinase C activity, decreased heparin sulfate proteoglycan, increased autooxidation, and changes in vasoactive substances such as endothelin, prostanooids, nitrous oxide, and histamine (see Chap. 13).⁴²

Aldose reductase-initiated accumulation of sorbitol has been hypothesized to lead to selective degeneration of mural cells in the retinal capillaries.⁴³ A second role of the polyol pathway in diabetic retinopathy may be its relationship to the development of abnormal basement membrane thickening,⁴⁴ which has been hypothesized to cause closure of retinal capillary vessels. This thickening can be prevented by aldose reductase inhibitors in galactosemic rats.⁴⁴ Results from clinical trials of aldose reductase inhibitors in galactosemic animals have not been consistent.⁴⁵ In a randomized controlled clinical trial in people with T1DM, an aldose reductase inhibitor, sorbinil, was not found to prevent the incidence or progression of early diabetic retinopathy.⁴⁶

The relationship of nonenzymatic or enzymatic glycosylation of proteins to the pathogenesis of retinopathy remains obscure. Clinical trials using aminoguanidine, which blocks glycosylation, have not shown the efficacy of this drug in preventing the progression of moderate to severe nonproliferative retinopathy.

Another proposed mechanism is abnormal release of growth hormone and growth factor changes (increased vascular endothelial and insulin-like growth factors) associated with impaired glucose metabolism.⁴⁷ Increased growth hormone has been hypothesized to result in plasma protein abnormalities (increases in alpha-2-globulins, fibrinogen, haptoglobins, and C-reactive proteins), which may be associated with increased plasma viscosity and decreased retinal blood flow. Using cell cultures, D'Amore and associates⁴⁸ have demonstrated that growth factors may be important in maintaining the integrity of retinal capillary endothelial and pericyte cells. Randomized controlled clinical trials using inhibitors of growth factors are now underway to determine their effect on the progression to proliferative retinopathy.

Whatever the cause, most proposed pathogenetic mechanisms are based on the assumption that retinal hypoxia is present early in the development of retinopathy.⁴⁹ Retinal hypoxia has been hypothesized to result from decreased oxygen release from hemoglobin, as has been reported by Ditzel and Standl in diabetic patients.⁵⁰ This has been attributed to decreased red blood cell 2,3-diphosphoglycerate, increased hemoglobin A_{1c}, and increased blood lipids.^{49,50} Another explanation for the development of hypoxia is that abnormalities in oxygen delivery result from altered retinal blood flow.^{11,49} Abnormalities in retinal blood flow have been found even before the development of ophthalmoscopically-visible diabetic retinopathy.⁵⁰ Kohner⁵¹ measured retinal blood flow based on an indicator dilution technique adapted to retinal blood vessels. She reported a decreased transit time of fluorescein dye and an increased volume flow in diabetic patients with no or early retinopathy

thy compared to normal controls. Increased blood flow has also been found in the renal, cerebral, and peripheral circulations in persons with diabetes.⁵² Kohner and colleagues have hypothesized that increased retinal blood flow may lead to damage of the retinal capillary pericytes and endothelial cells.⁵³

With the appearance of nonproliferative retinopathy, retinal blood flow has been reported to be decreased.⁵⁴ Reduction in retinal blood flow in diabetes has been hypothesized to result from abnormalities in plasma viscosity, platelet and red blood cell function, blood vessel wall structure and permeability, and autoregulatory mechanisms.^{10,49,50}

The initiation and progression of retinopathy is probably due to a complex relationship among a number of these factors, which vary at different stages in the natural history of retinopathy and from individual to individual. The pathophysiologic findings described above suggest that abnormalities in the diabetic microvasculature may play a primary role in diabetic retinopathy. Metabolic and physiologic alterations in the neuronal retina may also precede or accompany the circulatory changes. This is suggested by retinal functional abnormalities (e.g., color vision defects, electroretinogram changes, and delays in the visually evoked response) in diabetic patients without ophthalmoscopically detectable vascular retinopathy.^{55,56}

Why the microvasculature is differentially affected in different organs is still an unanswered question. Although the brain and retina are both neural tissue, it is rare to find microvascular abnormalities in the brains of diabetic patients.

Little is known about the processes responsible for the formation of new retinal blood vessels. Retinal ischemia and resultant hypoxia are hypothesized to liberate retinal angiogenic substances. A number of angiogenic substances have been identified as being present in retinal tissue, but their role in the development of retinal new vessels remains unclear.^{57,58} Also unclear is the role of the vitreous gel in inhibiting angiogenesis.

Epidemiology

Knowledge of the prevalence and incidence of diabetic retinopathy and various demographic, genetic, systemic, and ocular factors associated with retinopathy is of great importance in (1) efforts to prevent or modify the course of retinopathy; (2) characterization of the high-risk patient; and (3) estimation of health service needs. A number of epidemiologic studies have provided data about the natural history of diabetic retinopathy and its risk factors.^{16,17,35-38,40,41,59-89} Data from one such study, the WESDR, a large geographically defined population of both type 1 and type 2 diabetic persons examined in 1980-1982, in 1984-1986, and again in 1990-1992, and type 1 diabetic persons in 1995-1996 are presented to provide information on the incidence and prevalence of retinopathy.^{16,17,76-79} In addition, data from other epidemiologic studies are presented in Table 41-2.

Prevalence of Retinopathy

The prevalence and severity of diabetic retinopathy and macular edema in the baseline WESDR examination in 1980-1982 are presented in Table 41-3.^{16,17,90} The highest frequencies of any retinopathy (71%) and of proliferative retinopathy (23%) were found in the younger-onset group, diagnosed prior to age 30 years and taking insulin (n = 996), whereas the lowest frequencies of any retinopathy (39%) and proliferative retinopathy (3%) were

present in the older-onset group not taking insulin who were diagnosed with diabetes at or after 30 years of age ($n = 692$). While the proportions of proliferative retinopathy and macular edema were highest in the WESDR younger-onset group, the largest number of people with proliferative retinopathy or macular edema had older-onset diabetes (for proliferative retinopathy, 326 people in the older-onset groups compared with 240 people in the younger-onset group; for clinically significant macular edema, 272 people in the older-onset group compared with 56 people in

the younger-onset group). Similar differences in the prevalence of retinopathy in younger- and older-onset diabetes have been reported in other epidemiologic studies (Table 41-2). Based on the WESDR data, it is estimated that in 1980–1982, approximately 700,000 people in the United States with diabetes had proliferative retinopathy, 130,000 of whom had Diabetic Retinopathy Study (DRS) high-risk characteristics for severe visual loss of 5/200 or worse and 325,000 had clinically significant macular edema.

Incidence and Progression of Diabetic Retinopathy

The highest incidence and progression of retinopathy over the 10 years of the study were found in the younger-onset group, whereas the lowest incidence and progression were found in the older-onset group not taking insulin (Tables 41-4 and 41-5).^{76–78} In the younger-onset group, 89.3% without retinopathy and 29.8% without proliferative retinopathy at baseline developed retinopathy and proliferative retinopathy, respectively, by the time of the 10-year follow-up. The 10-year incidence of proliferative retinopathy was 10% in the older-onset group not taking insulin at baseline. The estimates of incident cases of proliferative retinopathy in the 10-year period are higher in the group with older-onset than in the group with younger-onset (387 versus 226). These data emphasize the need for timely referral and appropriate ophthalmologic care for people with older-onset diabetes.

Despite marked changes in the management of insulin-dependent diabetes over the 10-year follow-up period of the WESDR, there were few significant differences in the estimated annual incidence of proliferative diabetic retinopathy over the first 4 years of the study compared to the last 6 years of the study (Fig. 41-8). Based on the WESDR data, it is estimated that over the 10-year period, of the 5,800,000 Americans with known diabetes in 1980, 915,000 will have developed proliferative retinopathy, and 320,000 will have developed proliferative retinopathy with DRS high-risk characteristics.

Risk Factors for Diabetic Retinopathy

Race and Ethnicity

Recent data suggest differences in the prevalence and incidence of diabetic retinopathy among different racial and ethnic groups.^{35–37,77} Data from studies in Pima Indians and Oklahoma Indians with

TABLE 41-4. Ten-Year Incidence of any Retinopathy, Improvement or Progression of Retinopathy, or Progression to PDR* by Sex in People with Younger-Onset Diabetes (Type 1). Wisconsin Epidemiologic Study of Diabetic Retinopathy

Ten-Year	Male	Female	Total
No. at risk	142	119	261
Incidence of any retinopathy, %	93.0	84.9	89.3
95% CI	88.6, 97.4	78.2, 91.6	85.4, 93.2
No. at risk	184	200	384
Improvement, %	6.9	12.4	9.8
95% CI	3.1, 10.6	7.8, 17.1	6.7, 12.9
No. at risk	354	358	712
Progression, %	80.2	71.6	75.8
95% CI	75.8, 84.5	66.7, 76.4	72.5, 79.1

* PDR indicates proliferative diabetic retinopathy; CI, confidence interval. Number at risk for incidence of any retinopathy refers to the group that had no retinopathy (level 10/10) at the baseline examination and were at risk of developing retinopathy at the follow-up examination. Number at risk for improvement in retinopathy refers to those with retinopathy levels of 21/21 to 51/51 at the baseline examination who could have a decrease in their retinopathy severity by at least two steps or more at follow-up. Number at risk for no change, progression, or progression to PDR refers to those with retinopathy levels 10/10 to 51/51 who either did not change by two or more steps or progressed by two or more steps.

T2DM showed a higher risk of developing proliferative retinopathy than found in the non-Hispanic whites with T2DM in the WESDR. In addition, Pima Indians with T2DM are more likely to develop diabetic nephropathy than whites with this disease.⁹¹ The explanation for these differences is not clear. It is possible that Pima and Oklahoma Indians may have been exposed to longer periods of more severe hyperglycemia at a younger age than whites with T2DM.

Few studies have examined racial differences using similar protocols to measure risk factors and to detect diabetic retinopathy. One such study was the Third National Health and Nutrition Examination Survey (NHANES III), in which a representative population-based sample of people age ≥ 40 years in each of three racial/ethnic groups were examined.⁹² Prevalence of diabetic retinopathy in people with diagnosed diabetes was 84% higher in Mexican-Americans compared with non-Hispanic whites. Mexican-Americans also had higher rates of moderate and severe retinopathy and higher levels of many putative risk factors for retinopathy. While controlling for other measures of diabetes severity (duration of diabetes, hemoglo-

bin A_{1c} level, insulin and oral agent use) and systolic blood pressure, the risk of retinopathy in Mexican-Americans was twice that of non-Hispanic whites. Another such study, the San Antonio Study of Diabetic Complications, employed methods similar to those used in the WESDR.⁷¹ After controlling for other known risk factors, Mexican-Americans with T2DM in San Antonio had 1.7 times higher prevalence of any retinopathy than did non-Hispanic whites with T2DM in the WESDR. However, similar frequencies of retinopathy were found in Hispanic whites with T2DM in San Luis Valley, Colorado, and non-Hispanic whites with T2DM in the WESDR, suggesting that geographic and unmeasured factors may result in variations within similar ethnic groups.⁷³

Observations from clinical studies suggest a higher frequency of retinopathy in African-Americans attending ophthalmology clinics.⁹³ However, data from a recent study in St. Louis showed that the prevalence and incidence of retinopathy was lower in blacks than in whites with T1DM.⁹⁴ In the NHANES III, the prevalence of retinopathy was 46% higher in non-Hispanic blacks than in non-Hispanic whites.⁹² However, while controlling for measures of diabetes severity and blood pressure, non-Hispanic blacks were not at higher risk for retinopathy than non-Hispanic whites. These data suggest that differences in diabetes severity and glycemic control in persons with T2DM may explain black/white differences.

The prevalence of retinopathy in second-generation (Nisei) diabetic Japanese-Americans (12%) in Seattle was significantly lower than that reported in the diabetes clinic at Tokyo University Hospital (49% among patients with an onset of diabetes between 20 and 59 years of age and 47% among those with an onset after 59 years of age) and in diabetic white men not taking insulin reported in the WESDR (36%).⁸¹

There is a need to compare the distributions of known risk factors to explain the variations of retinopathy incidence and progression in different ethnic and racial groups. This is difficult because of variations from study to study in the detection and definition of diabetes and diabetic retinopathy.

Genetic

The relationships of specific genetic factors to increased susceptibility to diabetic retinopathy are not clear. Support for a

FIGURE 41-8. Estimated annual incidence of proliferative retinopathy in first 4 years and next 6 years in the younger-onset group taking insulin and the older-onset groups taking and not taking insulin in the Wisconsin Epidemiologic Study of Diabetic Retinopathy.

genetic relationship has come from studies that have shown that the severity and onset of retinopathy are similar among concordant identical twins.⁹⁵ In the Diabetes Control and Complications Trial (DCCT), familial clustering of diabetic retinopathy was investigated.⁹⁶ Familial associations were assessed by comparing the frequency of retinopathy in diabetic relatives of the respective positive versus negative DCCT subjects. There was an increased risk of severe retinopathy (odds ratio 3.1, 95% CI 1.2–7.8) among relatives of retinopathy-positive versus retinopathy-negative DCCT subjects among families of subjects with T1DM in the study. These findings suggest that severity of diabetic retinopathy is influenced by possible genetic factors.

Some studies have found relationships with various HLA antigens while others have not.^{97,98} In the WESDR younger-onset group, after adjusting for characteristics associated with proliferative retinopathy such as glycosylated hemoglobin, hypertension, duration of diabetes, and gross proteinuria, the presence of DR4 and the absence of DR3 were associated with a 5.4-fold increase in the odds of having proliferative retinopathy present compared with the absence of both DR4 and DR3.⁹⁹ However, in a 6-year follow-up of the same cohort, people with HLA-DR4 were less likely to have progression to proliferative retinopathy during the follow-up than those without this antigen (29.4% versus 43.5%). This relationship remained while controlling for other risk factors. The reasons for this discrepancy with prevalence and incidence data are not known. No other HLA antigens predicted the incidence and progression of retinopathy in the WESDR.

The reasons why specific HLA-DR antigens would increase the risk of developing more severe retinopathy are not apparent. Study of specific genetic factors associated with the pathogenesis of retinopathy, such as glycosylation, aldose reductase activity, collagen formation, and platelet adhesiveness and aggregation may yield a better understanding of the possible causal relationships between genetic factors and diabetic retinopathy.

There is a growing list of candidate genes involved in the pathogenesis of diabetic retinopathy that are being investigated. These include genes involved in inflammation, coagulation, vascular proliferation, glycosylation, metabolism of sugar (such as the polyol pathway), and in regulating vascular tone. Detection of such genes could result in the development of more specific therapeutic approaches for preventing the incidence and progression of retinopathy (see Chaps. 13 and 40).

Sex

Few differences in the prevalence and incidence of retinopathy in men and women with T1DM or T2DM have been reported. In the WESDR, there was a slightly higher prevalence of severe proliferative diabetic retinopathy with high risk for severe visual loss in younger-onset males (12%) compared to females (7%).¹⁶ The prevalence of proliferative retinopathy was similar in men and women with T1DM in Pittsburgh.⁸⁰

Time-Related Variables

Age and Puberty

It is rare to find signs of diabetic retinopathy in children who are less than 10 years of age, regardless of the duration of T1DM.^{16,100} After this age, the frequency and severity of retinopathy begins to increase. It has been hypothesized that a protective effect, lost after the start of puberty, is responsible for this.

In the WESDR, menarchal status at the time of the baseline examination was related to the prevalence and severity of retinopathy.¹⁰¹ After controlling for other risk factors, those who were post-menarchal were 3.2 times as likely to have retinopathy as those who were premenarchal. In a follow-up study of 60 insulin-dependent diabetic children, Frost-Larsen and Starup¹⁰² found the incidence of retinopathy to be higher after puberty than before, independent of duration or metabolic control of diabetes, or type of treatment. These findings have been observed in a number of other studies.^{103,104} Increases in growth hormone, insulin-like growth factor I, sex hormones, blood pressure, and poorer glycemic control (due to increased insulin resistance, poorer compliance, and/or inadequate insulin dosage) have been hypothesized to explain the higher risk of developing retinopathy after puberty. Age has less of an effect on the prevalence or incidence of diabetic retinopathy in older-onset diabetics. In the WESDR, few people 75 years of age or older with T2DM developed proliferative retinopathy over the 10 years of follow-up.⁷⁸

Duration of Diabetes

The frequency and severity of diabetic retinopathy, proliferative retinopathy, and macular edema increase with increasing duration of diabetes. The prevalence of retinopathy 3–4 years after diagnosis of diabetes in the WESDR younger-onset group with T1DM was 14.5% in males and 24% in females, and in all cases it was mild (Fig. 41-9).¹⁶ However, in persons with diabetes for

FIGURE 41-9. The frequency of retinopathy or proliferative retinopathy by duration of diabetes in years in 995 insulin-taking persons diagnosed to have diabetes before 30 years of age who participated in the Wisconsin Epidemiologic Study of Diabetic Retinopathy. (Reprinted with permission from Klein et al.¹⁶)

19–20 years, 50% of males and 33% of females had proliferative retinopathy. Early after diagnosis of diabetes, retinopathy was more frequent in the older-onset group compared with the younger-onset group (Fig. 41-10).¹⁷ In the first 3 years after diagnosis of diabetes, 23% of the older-onset group not taking insulin had retinopathy, and 2% had proliferative retinopathy. However, after 20 years of diabetes, fewer older-onset persons not taking insulin had retinopathy (60% versus 99%) or proliferative retinopathy (5% versus 53%) than younger-onset people.

Harris and coworkers¹⁰⁵ extrapolated data regarding retinopathy prevalence at different durations of diabetes from older-onset participants in the WESDR and in a study in Australia, to the time when retinopathy prevalence was estimated to be zero. They calculated that the onset of detectable retinopathy occurred about 4–7 years before diagnosis of T2DM in these populations.

In the WESDR, the prevalence of macular edema rose from zero in younger-onset persons with diabetes duration of 5 years to 21% in persons with diabetes duration of more than 20 years.⁹⁰ The prevalence of macular edema also varied with increasing duration of diabetes, ranging from 3% at 5 years to 13% at 15 years or more in noninsulin-taking patients. In a referral practice at the Joslin Clinic, macular edema was found to be more common (45%) in type 2 diabetic patients diagnosed after 40 years of age than in type 1 diabetic patients diagnosed after 40 years of age than in type 1 diabetic patients (17%) who were diagnosed before 30 years of age.¹⁰⁶

In the WESDR, the 4- and 10-year incidence of diabetic retinopathy increased with increasing duration of diabetes at baseline.^{76–78} The risk of developing retinopathy in the younger-onset group remained high (74%) even after 10 years of diabetes. The 4-year incidence of proliferative retinopathy varied from zero during the first 3 years after diagnosis of diabetes to 28% in younger-onset people with 13–14 years of diabetes. Thereafter the incidence remained stable.⁷⁶ This was also seen in a cohort of type 1 diabetic patients followed at the Joslin Clinic.¹⁰⁷ In the older-onset WESDR groups, 2% of those with less than 5 years' duration and 4.9% of those with 15 or more years of diabetes who were not taking insulin at baseline developed signs of proliferative retinopathy at the 4-year follow-up.⁷⁷

Data from other population-based studies describing the incidence and progression of diabetic retinopathy are presented in Table 41-2. Data from the WESDR and other studies suggest that prior to puberty or within 5 years of diagnosis, younger-onset persons with insulin-dependent diabetes do not need an ophthalmoscopic examination to detect proliferative retinopathy or macular edema.

Age at Diagnosis

Age at diagnosis was not related to incidence or progression of diabetic retinopathy in any of the diabetes groups followed in WESDR.^{76,77} However, after controlling for other risk factors in a cohort with T2DM in Rochester, Minnesota, the development of retinopathy was associated with younger age at diagnosis.³⁸

Control of Hyperglycemia

Review of the existing experimental literature using animal models leaves little doubt as to the strong relationship between glycemic control and less retinopathy.^{34,108,109} Epidemiologic studies have consistently demonstrated an association between glycemic control and the incidence and progression of diabetic retinopathy (Table 41-6).^{3,4,35–38,40,41,110,111} The WESDR demonstrated that lower blood sugar at any stage of retinopathy prior to the proliferative phase and at any duration of diabetes was associated with lower incidence and progression of retinopathy (Figs. 41-11, 41-12, and 41-13).³ However, the WESDR and other epidemiologic studies could not address the question of underlying severity of the diabetes, independently leading to both poorer control and more severe retinopathy. This could be addressed only in randomized therapeutic trials of metabolic control. The results of these trials suggest that achievement of glycemic control in individuals with previous poor control and nonproliferative retinopathy might be done slowly to potentially minimize the risk of progression to the more severe preproliferative or proliferative phase of the disease.

The DCCT was a large randomized controlled clinical trial in 1441 patients with type 1 diabetes.⁴ It showed that intensification of therapy reduced the risk of retinopathy.

FIGURE 41-11. Relation of 4-year incidence of diabetic retinopathy by quartiles of glycosylated hemoglobin at baseline in younger-onset persons taking insulin and older-onset persons taking and not taking insulin at baseline in the Wisconsin Epidemiologic Study of Diabetic Retinopathy. The ranges for baseline glycosylated hemoglobin in the younger-onset group (YO-I) are first quartile: 6.0–10.8%; second quartile: 10.9–12.2%; third quartile: 12.3–14.1%; and fourth quartile: 14.2–23.3%. The ranges for baseline glycosylated hemoglobin in the older-onset group taking insulin (OO-I) are first quartile: 6.9–10.1%; second quartile: 10.2–11.8%; third quartile: 11.9–13.4%; and fourth quartile: 13.5–19.2%. The ranges for baseline glycosylated hemoglobin in the older-onset group not taking insulin (OO-NI) are first quartile: 6.2–8.5%; second quartile: 8.6–9.8%; third quartile: 9.9–11.6%; and fourth quartile: 11.7–23.6%.

glycemic control was associated with a reduced risk of incidence and progression of retinopathy, progression to preproliferative and proliferative retinopathy, incidence of macular edema, and the need for panretinal photocoagulation compared to conventional insulin treatment (Table 41-7 and Fig. 41-14). These data indicate a favorable risk:benefit ratio for intensive glycemic control for most people with T1DM with no or early nonproliferative retinopathy. On

FIGURE 41-12. Relation of 4-year progression of diabetic retinopathy by quartiles of glycosylated hemoglobin at baseline in younger-onset persons taking insulin (YO-I) and older-onset persons taking (OO-I) and not taking (OO-NI) insulin at baseline in the Wisconsin Epidemiologic Study of Diabetic Retinopathy.

FIGURE 41-13. Relation of 4-year incidence of proliferative diabetic retinopathy by quartiles of glycosylated hemoglobin at baseline in younger-onset persons taking insulin (YO-I) and older-onset persons taking (OO-I) and not taking (OO-NI) insulin at baseline in the Wisconsin Epidemiologic Study of Diabetic Retinopathy.

average, 3 years were required to demonstrate the beneficial effect of intensive treatment. After 3 years, the beneficial effect of intensive insulin treatment increased over time. In addition, the DCCT data did not support the concept of a glycemic threshold regarding progression of retinopathy.

An early worsening of retinopathy in the first year of treatment of the intensive therapy group in the secondary-intervention cohort was observed. This finding was similar to those reported by earlier feasibility clinical trials of intensive treatment in patients with T1DM.¹¹²⁻¹¹⁴ The results suggest that achievement of glycemic control in individuals with previous poor control and nonproliferative retinopathy might be done slowly to potentially minimize the risk of progression to the more severe preproliferative or proliferative phase of the disease.

The United Kingdom Prospective Diabetes Study (UKPDS) was a randomized controlled clinical trial involving 3867 newly di-

agnosed patients with T2DM.^{5,115} After 3 months of diet treatment, patients with a mean of two fasting plasma glucose concentrations of 6.1–15.0 mmol/L were randomly assigned to an intensive glycemic control group with either a sulfonylurea (chlorpropamide, glibenclamide, or glipizide) or with insulin or a conventional glycemic control group with diet. After 10 years of follow-up, hemoglobin A_{1c} was 7.0% in the intensive group and 7.9% in the conventional group. Compared with the conventional group, the risk reduction for progression of diabetic retinopathy (defined as two or more steps on the ETDRS severity scale) over a 12-year period in the intensive group was 21%. In addition, there was a 29% reduction in the need for retinal photocoagulation in the intensive compared to the conventional group. These data conclusively showed that intensive treatment with either sulfonylureas or insulin significantly reduced the risk of progression of retinopathy in persons with T2DM.

C-Peptide Status

Data from studies regarding the relationship between endogenous insulin secretion in those with T2DM, independent of glycemic control, to retinopathy, are not consistent.¹¹⁶⁻¹¹⁸ After controlling for characteristics associated with retinopathy in the older-onset group with T2DM in the WESDR, there was no relationship between plasma C peptide and retinopathy.¹¹⁸ These findings suggest that the level of glycemia and not the level of endogenous C peptide is more important in determining the presence and severity of retinopathy in people with T2DM.

Exogenous Insulin

Exogenous insulin has been postulated to be a possible cause of atherosclerotic vascular disease and retinopathy in people with T2DM.¹¹⁹ In the WESDR, there was no association between the amount or type of exogenous insulin used and the presence and severity of retinopathy in the older-onset group using insulin whose C peptide was ≥ 0.3 nmol/L.¹¹⁸ These data suggest that exogenous insulin itself is probably not causally related to retinopathy in diabetic people with normal C peptide.

TABLE 41-7. Development and Progression of Long-Term Complications of Diabetes in the Study Cohorts and Reduction in Risk with Intensive as Compared with Conventional Therapy*

Blood Pressure

Because high blood pressure *per se* can cause many of the lesions associated with diabetic retinopathy (eg, cotton-wool spots, retinal hemorrhages, and microaneurysms), it is not unexpected that a positive association between blood pressure and severity of retinopathy has been reported by a number of investigators.^{16,17,59,62,63,67,71,73,75} Increased blood pressure, through an effect on blood flow, has been hypothesized to damage the retinal capillary endothelial cells, resulting in the development and progression of retinopathy.⁵³ The relative risk (RR) for the presence of retinopathy during the first 10 years of diabetes for the WESDR younger-onset insulin-taking persons with diastolic blood pressure in the highest quartile compared to those in the lowest quartile was about 2; for persons with 10 years or more of diabetes, the RR of proliferative retinopathy in persons whose diastolic blood pressure was in the highest quartile compared to those whose diastolic blood pressure was in the lowest quartile was also about 2.¹⁶ Similarly, the highest risk for retinopathy was reported for persons with highest blood pressure in the older-onset insulin- or noninsulin-taking persons.¹⁷

Macular edema has also been reported to be associated with increased blood pressure. Deutsch and associates¹²⁰ found that patients with macular edema in one clinic in the ETDRS had higher mean blood pressure than patients without edema. Similar findings have been reported in the WESDR for insulin- or noninsulin-taking persons.⁹⁰

In contrast to cross-sectional observation, data regarding the relationship between high blood pressure or hypertension and the development and progression of retinopathy have not yielded consistent findings (Table 41-6).^{35-38,40,41,121} In an 8-year follow-up of Swiss patients with T2DM, Teuscher and coworkers⁴⁰ found that those with uncontrolled hypertension were more likely to have their retinopathy progress than those whose blood pressure was controlled. In the WESDR, systolic blood pressure was a significant predictor of the 4-year incidence of diabetic retinopathy, diastolic blood pressure was a predictor for the 4-year progression of retinopathy, and both systolic and diastolic blood pressure were

predictors of the incidence of proliferative retinopathy, independent of glycosylated hemoglobin, only in people with younger-onset diabetes (Figs. 41-15 to 41-17).¹²¹ Neither systolic nor diastolic blood pressure was found to be related to the 4- or 10-year incidence or progression of retinopathy in either of the older-onset groups. The failure to find a relationship in the older-onset WESDR groups persisted after controlling for the use of antihypertensive medications.

Whether the relationship between blood pressure and retinopathy is etiologic or both are the result of the effect of diabetes on the microvascular system is difficult to assess from cohort studies. Data from the EURODIAB Controlled Trial of Lisinopril in T1DM (the EUCLID Study Group) study showed a 50% reduction in the

FIGURE 41-15. Relation of 4-year incidence of diabetic retinopathy by quartiles of systolic and diastolic blood pressure at baseline in younger-onset persons in the Wisconsin Epidemiologic Study of Diabetic Retinopathy. The ranges for baseline systolic and diastolic blood pressure, respectively, in the younger-onset group are first quartile: 78–110 and 42–71 mm Hg; second quartile: 111–120 and 72–78 mm Hg; third quartile: 121–134 and 79–85 mm Hg; and fourth quartile: 135–221 and 86–117 mm Hg.

PROGRESSION OF RETINOPATHY BY BLOOD PRESSURE

FIGURE 41-16. Relation of 4-year progression of diabetic retinopathy by quartiles of systolic and diastolic blood pressure at baseline in younger-onset persons in the Wisconsin Epidemiologic Study of Diabetic Retinopathy.

progression of retinopathy, after adjustment for glycemic control, in nonhypertensive or mildly hypertensive persons in the Lisinopril treatment group compared to the placebo group.¹²²

The UKPDS also sought to determine whether tight control of blood pressure with either a beta blocker or an ACE inhibitor was beneficial in reducing macrovascular and microvascular complications associated with T2DM.⁶ They randomized 1148 patients with hypertension (mean blood pressure 160/94 mm Hg) to a regimen of tight control with either captopril or atenolol and another 390 patients to less tight control of their blood pressure. Tight blood pressure control resulted in a 35% reduction in retinal photocoagulation compared to conventional control. After 7.5 years of follow-up, there was a 34% reduction in the rate of progression of retinopathy by two or more steps using the modified ETDRS severity scale, and a 47% reduction in the deterioration of visual acuity by three lines or more using the ETDRS charts (i.e., going from 20/20 to 20/40 or worse on a Snellen chart). The effect was largely due to a reduction in incidence of diabetic macular edema.

FIGURE 41-17. Relation of 4-year incidence of proliferative diabetic retinopathy by quartiles of systolic and diastolic blood pressure at baseline in younger-onset persons in the Wisconsin Epidemiologic Study of Diabetic Retinopathy.

PROGRESSION TO PDR BY BLOOD PRESSURE

Atenolol and captopril were equally effective in reducing the risk of development of these microvascular complications. The effects of blood pressure control were independent of glycemic control. These findings strongly support tight blood pressure control in people with T2DM as a means of preventing visual loss due to the progression of diabetic retinopathy.

Proteinuria and Diabetic Nephropathy

The prevalence and severity of diabetic retinopathy is associated with the presence of diabetic nephropathy, as manifest by microalbuminuria or gross proteinuria. This is not unexpected, as rheological, platelet, and lipid abnormalities associated with nephropathy may be involved in the pathogenesis of retinopathy.¹²³

Diabetic retinopathy is usually seen before clinical detection of nephropathy (measured by proteinuria, increased blood urea nitrogen [BUN], or serum creatinine), although physiologic manifestations of early renal dysfunction (e.g., increased glomerular filtration rate) may be detected early in the course of the disease. Differing underlying pathogenetic or anatomic factors have been postulated to explain such differences.¹²⁴ The higher frequency of retinopathy may also be secondary to its easier detection via ophthalmoscopy.

In the WESDR, gross proteinuria was present in 27% of insulin-taking persons diagnosed before 30 years of age who had retinopathy; for persons diagnosed at or after 30 years of age who were not taking insulin, gross proteinuria was present in 19% of those with retinopathy.^{16,17} In a study of diabetic Oklahoma Indians, West and colleagues⁶¹ reported that 58% of persons with severe retinopathy had heavy proteinuria.

In WESDR younger-onset persons with 10 years or more of diabetes, proliferative retinopathy was found three times as often in persons with proteinuria as in those without proteinuria; similarly, in noninsulin-taking older-onset persons, proliferative retinopathy was 2.7 times as frequent in the presence of proteinuria as in its absence.^{16,17}

In the WESDR, in the younger-onset group taking insulin, the RR of proliferative retinopathy developing over 4 years in those with gross proteinuria at baseline was 2.32 (95% CI 1.40, 3.83) compared with those without gross proteinuria.¹²⁵ For the older-onset group taking insulin, it was 2.02 (95% CI 0.91, 4.44), and for those not taking insulin it was 1.13 (95% CI 0.15, 8.50). After controlling for other risk variables, the relationship was of borderline significance ($p = 0.052$) in the younger-onset group with no or early nonproliferative retinopathy at baseline. In Pittsburgh, those with T1DM and microalbuminuria or overt nephropathy at entry had a significantly higher rate of progression to proliferative disease over a 2-year period than people without renal disease.⁴¹ These data suggest that gross proteinuria is a risk indicator for proliferative retinopathy and these patients might benefit from having regular ophthalmologic evaluation.

Most diabetic persons who develop end-stage renal disease that requires dialysis or transplantation have proliferative retinopathy. Ramsey and coworkers¹²⁶ reported that 75% of eyes of diabetic patients who were undergoing renal transplantation or dialysis had proliferative retinopathy, and 32% had visual acuity of 20/160 or worse in the better eye.

Patients on dialysis or following renal transplantation usually have a stabilization of visual function.¹²⁶ In one study, 54% (165/308) of eyes of diabetic patients had visual acuity of 20/50 or better at the time of their renal transplant for diabetic end-stage

renal disease. With a mean follow-up time of 3–5 years, 51% (157/308) of eyes had retained this visual acuity level. Progression of retinopathy was reported (no comparison group) in 38% (30/78) of eyes that had nonproliferative disease before transplantation. However, of eyes that had active proliferative retinopathy at the time of transplantation, 71% (43/61) became inactive and were at lower risk of visual loss after the transplantation. Similar findings were reported for patients on dialysis. However, patients undergoing transplantation are at risk of developing decreased visual acuity due to cataract formation, secondary to systemic corticosteroids, or due to cytomegalovirus retinitis (secondary to immunosuppression).¹²⁷

Patients undergoing hemodialysis have been thought to be at greater risk of vitreous hemorrhage due to heparinization or to rapid metabolic and blood pressure changes.¹²⁷ However, Ramsey and associates¹²⁶ reported no difference in visual prognosis (if metabolic and blood pressure control is brought about gradually) in diabetic patients managed by peritoneal dialysis compared to chronic hemodialysis. Patients undergoing hemodialysis are also at risk of developing increased intraocular pressure.¹²⁷ The mechanism for this is unknown. Monitoring of intraocular pressures of such patients is indicated.

Serum Lipids

Most of the information regarding the relationship of serum lipids to diabetic retinopathy is inconsistent (Table 41-6).^{37,41,67,73,128} In the WESDR, higher total serum cholesterol was associated with higher prevalence of retinal hard exudates in both the younger- and older-onset groups using insulin.¹²⁸ In the ETDRS, higher levels of serum lipids (triglycerides, LDL cholesterol, and VLDL cholesterol) were associated with an increased risk of developing hard exudates in the macula.¹²⁹ Randomized controlled clinical trials to investigate whether statins prevent the incidence and progression of retinopathy and visual loss are underway.

Smoking and Alcohol

Smoking, a known risk factor for cardiovascular disease, has been implicated in some studies as being causally related to retinopathy.^{85,130,131} One might anticipate such an association because smoking may cause tissue hypoxia by increasing blood carbon monoxide levels. Additionally, smoking may lead to increased platelet adhesiveness and aggregation. Paetkau and coworkers¹³⁰ first reported a positive association between smoking and proliferative diabetic retinopathy in 181 patients referred to a fluorescein angiography unit. Nielsen and Hjollund¹³¹ also found a relationship between severity of retinopathy and cigarette smoking in male, but not in female, T1DM patients. Many subsequent studies have failed to demonstrate an association between the risk of retinopathy and a smoking history.^{37,38,41,71,132,133} In the WESDR, cigarette smoking was not associated with the 4-year incidence or progression of diabetic retinopathy.¹³³

The few studies that have examined the relationship between alcohol consumption and diabetic retinopathy have not been consistent (Table 41-6).^{134–136} A possible protective effect of alcohol, as a result of reduced platelet adhesiveness and aggregation, might be expected. In the WESDR, alcohol consumption was associated with a lower prevalence of proliferative retinopathy.¹³⁶ However, there was no relationship between alcohol consumption at the 4-year examination and the incidence and progression of retinopathy 6 years later.

Body Mass (Obesity) and Physical Activity

The severity of retinopathy has been reported to be inversely correlated with body mass index in noninsulin-taking persons.^{17,61} This finding is compatible with the concept that obese older-onset noninsulin-taking patients have a milder form of the disease.

In the WESDR, there was no association between physical activity or leisure-time energy expenditure and the prevalence, incidence, and progression of diabetic retinopathy.¹³⁷ However, in women diagnosed to have diabetes before 14 years of age, those who participated in team sports were less likely to have proliferative diabetic retinopathy than those who did not.

Socioeconomic Status

There are few data available assessing the relationships between socioeconomic factors and severity of retinopathy. Hanna and colleagues¹³⁸ reported a significant association between proliferative retinopathy and occupational status (working class) or a lower income in a case-control study of 49 type 1 diabetic patients. West and coworkers⁶¹ failed to find a relationship of retinopathy with education level in a population of diabetic Oklahoma Indians. Haffner and associates¹³⁹ did not find a relationship between lower socioeconomic status (as measured using a combination of the Duncan Index, educational attainment, and income) and more severe retinopathy in 343 Mexican-Americans and 79 non-Hispanic whites with T2DM in San Antonio.

In the WESDR, with the exception of an association of lower incidence of proliferative retinopathy with more education in younger-onset women 25 years of age or older, socioeconomic status (education level and Duncan Socioeconomic Index score) was not related to increased risk of developing proliferative retinopathy.¹⁴⁰ Younger-onset men with proliferative retinopathy at baseline were more likely to become unemployed and younger-onset women were more likely to divorce 4 years later.

Pregnancy

In a review of the literature, Rodman and coworkers¹⁴¹ found that only 17 (8%) of 201 cases of pregnant diabetic patients with no or early nonproliferative retinopathy at the onset of their pregnancy progressed; only 4 of these 17 developed proliferative diabetic retinopathy. In 127 cases of women known to have proliferative retinopathy at the onset of their pregnancy, 32 (25%) experienced progression during the pregnancy. In a review of the Joslin Clinic data by Beetham¹⁴² in 1950, duration of diabetes before pregnancy was found to be the most important determinant of the progression of retinopathy.

Larinkari and associates¹⁴³ in an uncontrolled follow-up series of patients, observed progression of retinopathy in 8 of 42 pregnant diabetic patients. Progression of retinopathy was related to increased duration of diabetes, increased severity of retinopathy at the onset of disease, poor control of blood glucose during the first trimester, and higher serum progesterone concentrations. In a prospective study, Moloney and Drury¹⁴⁴ reported a 40% incidence of retinopathy in patients who were free of retinopathy at the beginning of the pregnancy. There was zero incidence of retinopathy in 120 nonpregnant insulin-dependent control subjects. In patients with background retinopathy at the onset of their pregnancies, progression, manifested by streak or blot hemorrhages, occurred in 53%, and cotton-wool spots occurred in 29%. In comparison,

streak or blot hemorrhages occurred in only 8% and soft exudates in none of the diabetic nonpregnant control group. Only one of the pregnant women with nonproliferative retinopathy progressed to proliferative disease. In the pregnant group, ophthalmoscopic manifestations of retinopathy disappeared in 12 (23%) patients after delivery. Development of streak and blot hemorrhages was associated with increased insulin requirement and higher fasting blood glucose and hemoglobin A₁ levels early in pregnancy. Soft exudates were associated with lower fasting blood glucose levels late in pregnancy, but not with hypertension or preeclamptic toxemia.

In a recently completed case-control study of women with T1DM, the frequency of progression to proliferative retinopathy was higher in those who were pregnant compared to those who were not (7% versus 4%).¹⁴⁵ Women in this study were similar in age, duration of diabetes, and retinopathy status at baseline. Pregnancy remained a significant predictor of the progression of diabetic retinopathy after controlling for glycosylated hemoglobin and blood pressure.

With the development of photocoagulation, there has been much change in the management of female diabetic patients since 1950, when Beetham recommended that "in their own best interests, patients presenting a large amount of retinal hemorrhage, or proliferating retinopathy, should not be permitted to undertake pregnancy."¹⁴² Current management recommendations include evaluation by an ophthalmologist of all type 1 diabetic patients considering pregnancy or those who have become pregnant. Those women with no or mild retinopathy, although at low risk of progression, should be followed by an ophthalmologist and seen more frequently than usual during gestation (perhaps every 2–3 months), especially if they develop complications (e.g., toxemia or progression of retinopathy). Because panretinal photocoagulation has been shown to cause significant regression of retinal new blood vessels and prevent serious reduction of vision, women with severe preproliferative or proliferative retinopathy should be referred for possible treatment.⁷ There are no data on the benefits of cesarean section as a means of delivery for women with high-risk proliferative retinopathy who do not respond to panretinal photocoagulation treatment.

Severe retinopathy has been shown to be an indicator of higher risk of congenital abnormalities in children born of mothers with T1DM.¹⁴⁶

Retinopathy, Comorbidity, and Mortality

Severe retinopathy is associated with cardiovascular disease risk factors such as increased fibrinogen, hyperglycemia, hypertension and increased platelet aggregation.⁸⁰ This probably explains in part why people with diabetic retinopathy have been found to have higher prevalence of coronary disease.⁶¹ Thus it is not surprising that in the WESDR, those with proliferative retinopathy were at increased risk of developing a heart attack, stroke, diabetic nephropathy, and amputation (Table 41-8).

The ETDRS demonstrated that aspirin does not increase the risk of vitreous hemorrhage or loss of vision in persons with proliferative retinopathy.¹⁴⁷ It was also not found to prevent the incidence or progression of retinopathy in the WESDR or the ETDRS.

The probability for survival decreases with increasing severity of retinopathy. In the WESDR, increasing risk of death was found with more severe retinopathy at baseline (Figs. 41-18 and 41-19). These findings are consistent with the association of severe retinopathy with the incidence of cardiovascular disease and diabetic nephropathy. The higher prevalence of systemic conditions (e.g., uremia, coronary heart disease, and hypertension) in patients with severe retinopathy is responsible for the increased risk of death. These data suggest that diabetic patients with retinopathy should be under close medical surveillance for diagnosis and treatment of cardiovascular disease.

Medical Therapy

Aside from oral hypoglycemic agents, insulin, and antihypertensive medications, no drugs have been found to prevent or decrease the progression of diabetic retinopathy.^{2,148} Treatment regimens involving androgenic and nonandrogenic anabolic steroids; vitamins B₁, C, E, and K; calcium debosilate; calcium phosphate; cyclandelate; anticoagulants; aldose-reductase inhibitors; and aspirin have been proposed, tried, or have not proved to be of therapeutic or preventive value in altering the course of diabetic retinopathy.^{2,46,147,148}

Epidemiologic studies, the DCCT, and the UKPDS have clearly demonstrated the significant reduction in the incidence and progression of diabetic retinopathy by reduction of hyperglycemia.^{4,5} The findings from the DCCT and UKPDS have stron

public health importance, as only 6.7% of the younger-onset persons, 9.5% of older-onset persons taking insulin, and 34.8% of older-onset persons not taking insulin in the WESDR had glycosylated hemoglobin levels at the baseline examination that fell within two standard deviations from the mean of a nondiabetic comparison group.³ Ten years after the baseline examination, data from the WESDR continue to show a large number of individuals with poorly controlled diabetes.¹⁴⁹

The results of the UKPDS and from EUCLID clinical trials suggest that control of blood pressure may also reduce the progression of diabetic retinopathy independent of glycemic control.^{6,122} Data from the WESDR also show a significant proportion of people with diabetes whose hypertension is in poor control.

Surgical Therapy

Photocoagulation

The rationale for the use of panretinal photocoagulation resulted from the observation that the eyes of diabetic patients with

FIGURE 41-19. disseminated chorioretinal scars due to trauma or infection had lower rates of retinopathy than the fellow eye without such changes.² As a result of these observations, high-energy light sources (xenon arc; ruby, argon, and krypton lasers) have been developed to produce burns leading to scars in the outer layer of the retina.

Despite a number of clinical studies, five of which used concurrent controls, the efficacy of photocoagulation in preventing severe visual loss due to proliferative retinopathy was not widely accepted prior to the onset of the Diabetic Retinopathy Study (DRS) in 1972. That therapeutic trial was sponsored by the National Eye Institute and was conducted between 1972 and 1979.⁷ A total of 1758 patients were involved. To be eligible for participation, patients had to have visual acuity of 20/100 or better in each eye, no previous photocoagulation, and proliferative retinopathy in at least one eye or severe nonproliferative or proliferative retinopathy in both eyes. There was random assignment of one eye of each patient to photocoagulation (either xenon arc or argon laser) and the other to follow-up without photocoagulation. The photocoagulation technique involved "scatter" panretinal photocoagulation of retinal new vessels.

The major end point in the DRS was "severe visual loss," defined as a visual acuity of less than 5/200 in two consecutive follow-up visits 4 months apart. The major finding of the DRS was that the risk of severe visual loss in treated eyes was less than one half that in untreated control eyes (Fig. 41-20).⁷ The 6-year cumulative event rate for severe visual loss was 38% for untreated and 16% for treated eyes. High-risk retinopathy characteristics for severe visual loss in untreated eyes in the DRS included new vessels at the optic disk equaling or exceeding one-third of the disk area in extent (Fig. 41-21), new vessels at the disk less than one-third of the disk area in extent with preretinal or vitreous hemorrhage, and new vessels more than one disk diameter away from the optic disk greater than one-half the disk area in size associated with preretinal or vitreous hemorrhage. The conclusion reached by the DRS group was that in eyes with such high-risk characteristics, the risk of severe visual loss without treatment was 25% at 2 years and in eyes with treatment it was 12%; this beneficial effect outweighed the risk of harmful treatment effects.⁷ The results of the ETDRS suggested that earlier panretinal treatment of eyes with high-risk proliferative retinopathy may result in a 90% decrease in the risk of severe loss of vision.¹⁵⁰

The ETDRS provided data on panretinal photocoagulation treatment for eyes in which proliferative retinopathy with DRS high-risk characteristics for severe vision loss were not present.¹⁵¹ The data suggest that in eyes with early or moderate severe nonproliferative retinopathy (Levels 21-47; see Table 41-1) there is little or no reason to treat with panretinal photocoagulation because of the relatively low risk of progression to severe visual loss and the risk of complications associated with such treatment. However, in people in whom both eyes have bilateral severe preproliferative retinopathy or proliferative retinopathy without DRS high-risk complications (Level 53 or 65; see Table 41-1), the data suggest there may be some benefit in prompt initiation of panretinal photocoagulation in at least one eye.

Before undergoing panretinal treatment, the patient is told that photocoagulation may reduce the chances of severe loss of vision (to less than 5/200), but that it does not completely eliminate its possibility. The patient is also told that photocoagulation may cause moderate reduction of visual function as an unavoidable side effect, but that this reduction usually is of minor consequence. Such

FIGURE 41-20. Cumulative rates of severe visual loss (5/200 or less) in the Diabetic Retinopathy Study Group. (Reprinted with permission from Diabetic Retinopathy Study Group.⁷)

reduction includes mild loss of central vision (e.g., if the visual acuity was 20/20 before treatment, it might be reduced to 20/25 to 20/30 after panretinal argon laser treatment in 10% of patients), mild constriction of peripheral visual fields (5% of cases with argon laser), impaired night vision, and decreased accommodation.^{7,152} The patient is also informed about the rare more severe side effects (e.g., severe constriction of visual fields and severe loss of central vision due to development of vitreous hemorrhage, traction retinal detachment after treatment, or an inadvertent foveal burn).

Panretinal photocoagulation is usually done as an outpatient procedure. To achieve anesthesia, proparacaine drops are applied to the cornea. Rarely, a retrobulbar injection of lidocaine is used. The pupil is dilated, and a contact lens is applied to the cornea. Under

direct visualization of the retina, 800–1800 burns, usually 500- μ m diameter in size, are delivered in a grid-like pattern (sparing the central retina) in one or more treatment sessions (Fig. 41-22). A successful treatment usually leads to partial or complete regression of abnormal new preretinal and optic disk blood vessels (Fig. 41-23), in most cases within 4 weeks. If the high-risk characteristics remain, further treatments are usually scheduled. Underlying reasons for failure to respond to laser treatment were not defined in the DRS.

The mechanisms of action of panretinal photocoagulation are not known. A number of theories of how photocoagulation works have been suggested. They include destruction of hypoxic retinal tissue resulting in decreased production of a hypothetical va-

FIGURE 41-21. Fundus photograph of the left eye showing stringy new vessels equaling one-third the disk area in front of the optic disk (**black arrows**). This patient, who is asymptomatic and has normal visual acuity, is at high risk of developing severe visual loss if not treated with panretinal photocoagulation. Saunders:1983.)

soproliferative factor, increased oxygenation of untreated retinal tissue leading to vasoconstriction and regression of proliferative tissue, and increased passage of metabolites through the blood-retinal barrier at the level of the retinal pigment epithelium.^{10,11}

The ETDRS has demonstrated that treatment of clinically significant macular edema with focal or grid (or both) laser photocoagulation of the macular area reduces doubling of the visual angle (e.g., going from 20/20 to 20/40 or 20/30 to 20/60) to 13% from 30% in untreated eyes (Fig. 41-24).⁸

During treatment for macular edema, a fluorescein angiogram projected on a wall or in a special viewer is used to demonstrate abnormal leakage from retinal blood vessels, which may be responsible for macular edema, as well as for areas of ischemia (closure of retinal capillaries). Topical anesthesia with proparacaine drops is routinely used. Photocoagulation burns of 0.05–0.1 second duration and 100–200 μ m in size are directed at leaking retinal microaneurysms as identified on the fluorescein angiograms. Burns of 50 μ m may be added to achieve further whitening of the retinal microaneurysms. Nonperfused areas may also be treated in a grid-like pattern to destroy ischemic retina. Follow-up examination is done within 3 months; if the edema persists, the angiogram is repeated and any remaining leaks are treated.

The rationale for photocoagulation for macular edema includes ablation of leaking microaneurysms. Bresnick²² has suggested that a “debridement” of abnormal retinal pigment epithelial cells with replacement by normal cells may reestablish the blood-retinal barrier, facilitating absorption of retinal edema fluid.

Vitrectomy

Vitrectomy is done to remove vitreous hemorrhage or to cut fibrous bands that cause tractional detachments of the retina due to proliferative disease. Prior to the development of vitrectomy, the only treatment for vitreous hemorrhage was patching of both eyes and elevation of the head. Currently, if a significant vitreous hemorrhage obscures visualization of the retina, bilateral patching and

elevation of the head for 24–48 hours is sometimes recommended. The fundus is examined, and if there has been enough settling of the vitreous hemorrhage, panretinal photocoagulation is done if indicated and feasible.

Vitrectomy may be recommended if there has been no clearing of the vitreous hemorrhage after a few months in people with T1DM or after 6–12 months in people with T2DM, or sooner if there is ultrasound or other evidence of a tractional retinal detachment threatening or involving the macular area. The major objectives of vitreous surgery are to clear the optical axis of opacities and to release mechanical traction on the retina.

Vitrectomy is a procedure that may require hospitalization and may be performed under general anesthesia; the average duration of the operation is 2–3 hours. Because the surgery is generally performed on an elective basis, preoperative evaluation includes a thorough examination to diagnose and control numerous medical problems often found in the diabetic patient undergoing vitrectomy. Cardiovascular, renal, and metabolic problems must be managed during and after surgery.

The vitrectomy device and fiberoptic illuminators are introduced into the eye through small openings made in the sclera overlying the pars plana (flat portion) of the ciliary body. Usually the lens is left undisturbed; however, if a cataract is present and prohibits visualization for vitrectomy, the lens may be removed before or during surgery. Under direct observation, the vitrectomy instrument is used to cut and remove fibrous tissues and blood from the vitreous cavity, and vitreous volume is restored with a balanced salt solution. Using special intraocular scissors, the surgeon may cut fibroproliferative tissue and epiretinal membranes, which are responsible for traction on the retina.

In cases in which a prior retinal tear is present or a tear occurs during the procedure, choroidoretinal adhesion is produced around the tear with cryopexy to prevent detachment of the retina. Additionally, air with or without expanding gas mixtures (e.g., sulfur hexafluoride) may be exchanged for the fluid in the vitreous cavity

A

B

FIGURE 41-23. A. Fundus photograph of the left eye demonstrating extensive retinal new vessels in front of the disk and preretinal hemorrhage (white arrowheads). B. Four weeks after panretinal argon laser photocoagulation there has been a dramatic regression of retinal new vessels. Pigmented photocoagulation scars are present in the periphery of the picture. (Reprinted with permission from Klein R: *Management of eye disease in the insulin-dependent diabetic patient*. In: MacDonald M, ed. *Managing Diabetes Mellitus in Children and Adolescents*. Saunders:1983.)

to tamponade the retinal tear, and the subretinal fluid may be drained during the operation. Scleral buckling (with hard episcleral silicone or sponges) may also be used to indent the sclera, reduce traction further, and thus seal the tear.

In a series of patients undergoing vitrectomy, visual improvement to better than 20/200 was reported in 50% of operated cases.¹⁵³ Michaels¹⁵⁴ described a series of 596 consecutive eyes with severe loss of visual acuity and reported a successful result (visual acuity of 5/200 or better and stable anatomic findings) in 384 (66%) of 579 eyes. Successful results after vitrectomy are more likely in

eyes with vitreous hemorrhage alone than in eyes with traction retinal detachment involving the macular area. In the latter, the effects of preexisting anatomic damage to the macular area are more likely to limit visual improvement postoperatively.

Vitrectomy carries with it a number of serious complications, which include iatrogenic retinal tears resulting in retinal detachment, recurrent vitreous hemorrhage, corneal edema, cataract, the development of neovascularization of the iris and rubeotic glaucoma.¹⁵⁵

Rubeotic glaucoma (secondary to neovascularization of the anterior chamber angle), when it occurs, usually develops within

FIGURE 41-24. Comparison of percentage of eyes that experienced visual loss of 15 or more letters (equivalent to at least doubling of initial visual angle or loss of three or more lines) in eyes with macular edema and mild to moderate diabetic retinopathy assigned to either immediate focal photocoagulation (**dashed line**) or deferral of photocoagulation (**solid line**). Z stands for normal deviate. (Reprinted with permission from ETDRS Research Group.⁸)

6 months of vitrectomy and is more likely to arise in eyes with severe retinal ischemia, retinal detachment, or removal of the lens. Panretinal photocoagulation during (using an endophotocoagulator) or after the procedure may reduce the incidence of this serious complication.

The Diabetic Retinopathy Vitrectomy Study (DRVS) assessed indications, risks, and benefits for early (shortly after the development of vitreous hemorrhage) versus late (a year) vitrectomy.¹⁵⁶ The rationale for early vitrectomy included avoiding prolonged visual disability and possibly avoiding the presumed deleterious effects of long-standing intraocular hemorrhage (possible acceleration of growth of fibroproliferans, exacerbation of retinal vascular occlusive process, and a possible toxic effect of blood on the retina). The rationale for late vitrectomy (at least 1 year after the initial vitreous hemorrhage) included the possibility of spontaneous resolution of hemorrhage and that with time the retinopathy would be stabilized and there would be fewer vision-threatening complications of surgery (e.g., neovascular glaucoma). The DRVS showed that there was a significant benefit in terms of restoring visual acuity by early vitrectomy in those with T1DM.

VISUAL IMPAIRMENT

Diabetes is an important cause of impaired vision.^{1,157} It is estimated to account for 5000 new cases of legal blindness (visual acuity of 20/200 or worse in the better eye) in the United States each year. Blindness is 29 times more common in diabetic than in non-diabetic persons (Fig. 41-25). Approximately 8% of people who were legally blind reported diabetes as the etiology of their blindness,¹⁵⁸ and it is estimated that in the United States, more than 12% of new cases of blindness are attributable to diabetes.

Prevalence

The prevalence of blindness in diabetic persons is related to current age.¹⁵⁹ In the WESDR, prevalence of diabetes-related legal blindness increased with increasing age. No cases of legal blindness were found in persons younger than 25 years of age. The prevalence of legal blindness increased in both males and females,

FIGURE 41-25. Percentage of persons with visual acuity of 20/200 or worse in the better eye in the Wisconsin Epidemiologic Study of Diabetic Retinopathy, Health and Nutrition Examination Survey, and the Framingham Eye Study by current age. (Reprinted with permission from Klein et al.¹⁵⁹)

VISUAL ACUITY 20/200 OR WORSE IN BETTER EYE IN DIFFERENT POPULATIONS

TABLE 41-9. Ten-Year Incidence of Blindness, Visual Impairment, and Doubling of the Visual Angle

Group	Blindness		Visual Impairment		Doubling of the Visual Angle	
	N	%	N	%	N	%
Younger-onset	868	1.8	832	9.4	880	9
Older-onset, taking insulin	465	4.0	423	37.2	472	32
Older-onset, not taking insulin	490	4.8	454	23.9	494	21

Source: Moss *et al.*²⁷

reaching peaks of 14% and 20%, respectively. In the older-onset WESDR group, prevalence of blindness increased with increasing age and accounted for 1.6% in persons taking insulin and 2.2% in those not taking insulin. In a study in Oxford, England, in 1982, 28% of the 188 people 60 years of age or older with known T2DM were visually impaired.¹⁶⁰ The age-specific prevalence of legal blindness in both younger- and older-onset diabetic patients in the WESDR was significantly higher than those estimated for the general United States population in the Health and Nutrition Examination Survey (HANES) or for all participants in the Framingham Eye Study (Fig. 41-25).^{158,161,162}

In the WESDR, legal blindness was related to duration of diabetes in both younger- and older-onset groups. In the younger-onset group, legal blindness first occurred in persons having diabetes for about 15 years or more and increased from 3% in those with 15–19 years' duration to 12% in persons with diabetes for 30 or more years. In the older-onset groups, prevalence of legal blindness was lower, only reaching 7% in persons having diabetes for 20–24 years.

In the WESDR, diabetic retinopathy was partially or totally responsible for legal blindness in 86% of eyes of younger-onset persons and in 33% of eyes of older-onset persons with such impairment.

Incidence

In persons 20–79 years of age with T2DM who participated in the University Group Diabetes Program, the 5-year incidence of legal blindness was 4% or less in each treatment group.¹¹¹ The incidence of 20/200 or worse visual acuity in either eye was 9% or less in each treatment group at the 5-year follow-up, and rose to about 12% at the 12-year follow-up. Review of earlier data from diabetic patients attending the Radcliffe Infirmary in England provided esti-

mates of incidence of blindness.² In diabetic patients diagnosed at 20 years of age, the incidence of blindness was 0.1% after 10 years; 1.6% after 20 years, and 3.5% after 30 years of diabetes. For persons diagnosed at 60 years of age, the incidence of blindness was 1.8% after 10 years and 5.5% after 20 years of diabetes. Sjölie and Green¹⁶³ reported an 8-year incidence of 7.6/1000 patient-years in males and 10.2/1000 patient-years in females with T1DM. In Oxford, England, 4.8% of those with T2DM who were 60 years of age or older at baseline became legally blind over a median period of 6 years.¹⁶⁰

The 10-year incidence of blindness and impaired vision in the WESDR are presented in Table 41-9. The older-onset group taking insulin had the highest 10-year incidence of visual impairment (37.2%). The estimated annual incidence of blindness reported in the WESDR was 3.3 per 100,000 population.¹⁵⁷

There are few studies that permit determination of trends in the frequency of decreased vision over time. Two studies in England compared rates of registration for blindness benefits attributed to diabetic retinopathy in 1985 with those recorded in England by Sorsby in 1965.^{164–166} In Avon the rates remained unchanged over this period while in Leicestershire there was a significant decrease. In the WESDR, the cohort was reexamined 10 years after the baseline examination.²⁷ There appeared to be a decrease in the estimated annual incidence of blindness in the three WESDR diabetic groups in the last 6 years compared to the first 4 years of the study (Table 41-10). The decrease in the estimated annual incidence of blindness is not explained by changes in the incidence of proliferative retinopathy or an increased frequency of panretinal photocoagulation in the second 6-year period. Higher frequencies of focal photocoagulation for macular edema and lens extraction for cataract in the second 6-year period of the study compared to the first 4 years may explain only part of the decrease in frequency of blindness over time.

TABLE 41-10. Estimated Annual Incidence of Blindness, Doubling of the Visual Angle, and Proliferative Retinopathy in the Periods 1980–1982 to 1984–1986 and 1984–1986 to 1990–1992

End Point	Period	Younger-Onset %	Older-Onset	
			Taking Insulin %	Not Taking Insulin %
Blindness	1980–1982 to 1984–1986	0.38	0.82	0.67

Risk Factors for Impaired Vision

Diabetic Retinopathy

Eyes with more severe retinopathy have been found to be at higher risk of blindness. The cumulative 5-year rate of blindness (visual acuity of 20/200 or worse) for eyes with good vision (20/60 or better) at the beginning of one study was 2% if retinopathy was not present and 15% if retinal blot hemorrhages, exudates, or both were present.¹⁶⁷ Untreated eyes in the DRS had a cumulative event rate of severe visual loss (less than 5/200) of 14% at 2 years, 27% at 4 years, and 38% at 6 years (Fig. 41-20).⁷ In the WESDR, the 4-year incidence of doubling of the visual angle increased with increasing severity of retinopathy at baseline (Fig. 41-26).¹⁵⁷ In the WESDR, the 4-year incidence of doubling of the visual angle was increased in the presence of macular edema at baseline (RR 3.5, 95% CI 1.8, 6.9 in the younger-onset group; RR 2.8, 95% CI 1.8, 4.3 in the older-onset group taking insulin; and RR 5.6, 95% CI 3.2, 9.6 in the older-onset group not taking insulin).

In insulin-dependent younger-onset persons, reduction of vision to 20/200 or worse is more likely to be due to proliferative retinopathy resulting in vitreous hemorrhage or retinal traction detachment involving the macular area.¹¹ In older-onset persons, similar visual loss in patients with retinopathy is often associated with macular edema.^{11,159} In both groups, macular ischemia due to closure of retinal capillaries in the foveal area may also result in a decrease of vision.^{10,11}

If proliferative diabetic retinopathy is present, vitreous hemorrhage from fragile abnormal new preretinal blood vessels may result in an acute decrease in vision. In such cases the sudden appearance of a number of small dark floaters, a large spot obscuring vision, or "complete" loss of vision is described. Contraction of fibrous proliferative tissue leading to traction on the macular area may cause distortion in vision. Traction on the retina may also result in retinal detachment; if the macula is involved, severe blurry vision and darkening of vision may result. In some diabetic patients there may be marked fluctuations in vision due to clearing and recurrence of vitreous hemorrhage or macular edema.

In older diabetic patients with macular edema, the visual disturbance may go unnoticed until both eyes are involved. The patient may complain of a blur or distortion in central vision, especially when reading. In the absence of proliferative retinopathy, patients with diabetic maculopathy and loss of central vision are usually left with peripheral vision that is sufficient to navigate, unless glaucoma or severe cataracts are present.

Other Risk Factors for Impaired Vision

In addition to age, duration of diabetes, severity of retinopathy, higher glycosylated hemoglobin, and gross proteinuria were associated with increased 4-year risk of doubling of the visual angle in the WESDR.¹⁵⁷ In the UKPDS, after 9 years of follow-up, tight blood pressure control reduced the risk of doubling of the visual angle by 47%.⁶

Impaired Color Vision

Diabetic patients as a group have poorer color vision than nondiabetic persons. Even before the development of retinopathy, disturbances in yellow-blue hue discrimination may be detected.⁵⁶ With progression of maculopathy, manifested by edema or hard exudate, further deterioration in color vision is found. This has therapeutic significance because many patients using home blood glucose

FIGURE 41-26. Four-year incidence of doubling of the visual angle by baseline retinopathy severity (see Table 41-1 for definitions) in the Wisconsin Epidemiologic Study of Diabetic Retinopathy in **A (top panel)** the younger-onset group, **B (center panel)** the older-onset group taking insulin, and **C (bottom panel)** the older-onset group not taking insulin.

monitoring may have difficulty correctly interpreting results of glucose testing. If an impairment in color vision exists, use of alternate devices (e.g., meters with digital display of glucose concentration) when testing glucose should be considered.

Other Causes of Impaired Vision

A frequent cause for sudden change in vision, especially in children and adolescents with diabetes, is related to a change in a refractive medium.² In adults this may be one of the presenting symptoms at the time of diagnosis. The patient may complain of blurriness in vision, which can usually be corrected to 20/20 or

better with appropriate glasses. Reversible osmotic swelling of the lens due to rapid alterations in blood sugar has been postulated to be responsible for this phenomenon. With better control of the blood sugar, the refraction and acuity return to previous levels.

Cataract

Cataractous lens changes often cause a decrease in vision.² This affects a small percentage of young T1DM patients, but occurs more frequently than in age-matched nondiabetic persons. Cataracts in young diabetic patients have been described as vacuolar or snowflake in appearance, involving the cortical or posterior subcapsular area of the lens. In the young, rapidly progressive cataracts have been associated with poor control.² It has been suggested that high glucose concentrations in the aqueous humor surrounding the lens enter lens cells and are converted to sorbitol in the polyol pathway.¹⁶⁸ Sorbitol cannot leave the lens cells and so accumulates, leading to osmotic swelling and destruction of cells. The use of aldose-reductase inhibitors has been found to inhibit such cataract formation in poorly controlled diabetic animals.

Prevalence rates of cataracts have been reported to increase with increasing age and are higher for diabetic than nondiabetic persons for each age.^{2,169} The association between cataracts and diabetes is stronger at younger ages. In the Beaver Dam Eye Study, after adjusting for age and sex, one type of cataract, cortical opacities, was significantly more common among people with older-onset diabetes compared to the rest of the nondiabetic Beaver Dam population.¹⁷⁰ Posterior subcapsular cataract, another type of lens opacity, was more common in people with diabetes, but the increase was not significant in all age groups. Longer duration of diabetes was associated with increased odds of all kinds of cataracts.

In the WESDR, multivariate analyses indicated that age and duration of diabetes were the most important risk factors for cataract presence. Severity of diabetic retinopathy was associated with a small but significant further increase in risk.¹⁷¹ In younger-onset persons, diuretic use and glycosylated hemoglobin were also associated with increased risk. In older-onset persons, diuretic use, intraocular pressure, smoking status, and diastolic blood pressure were associated with increased risk of cataract.

Burditt and Caird¹⁷² found a relationship between metabolic control of blood sugar and the frequency of lens opacity for middle-aged men. In the UKPDS, there was a 34% reduction in cataract extraction in those in the intensive glycemic control group compared to the conventional treatment group.⁵ These data suggest that glycemic control in persons with T2DM may reduce the progression of cataracts. Potential environmental exposures may also affect rates of cataracts. One such exposure, to aspirin, has not been shown to reduce the prevalence of cataracts in eyes of people with diabetes.^{173,174}

If a cataract causes significant visual impairment, the patient may no longer be able to read. Cataract extraction, if successfully performed, usually results in good vision with the use of glasses or contact lenses, assuming that concomitant retinopathy has not affected central vision.

Cataract extraction is a frequent occurrence in people with diabetes. In prevalence data from the WESDR, 3.6% of younger-onset and 8.7% of older-onset persons had such surgery.¹⁷¹ In the Beaver Dam Eye Study, there were higher frequencies of past cataract surgery in people with diabetes in each age group.¹⁷⁰

Cataract surgery has been found to be associated with progression of diabetic retinopathy in some studies. Jaffe and Burton¹⁷⁵ reported subsequent progression of the severity of retinopathy in the

operated eye of patients with nonproliferative retinopathy prior to cataract extraction. However, others did not find cataract surgery to be associated with progression of retinopathy.¹⁷⁶

Results of clinical surveys suggest that intraocular lens implants may be used without excess morbidity to the eye in some diabetic patients with no or early nonproliferative retinopathy.¹⁷ Straatsma and coworkers¹⁷⁷ reported no difference in complications or final postoperative visual acuity level between diabetic and nondiabetic patients. They recommended use of an intraocular lens only in diabetic patients 60 years of age or older with a cataract related decrease in vision that interfered with the patient's activities and if proliferative diabetic retinopathy or rubeosis was not present. These lenses are now commonly used even at younger ages if there are no contraindications present.

Glaucoma

Glaucoma is a disease in which there is loss of vision or visual field from damage to the optic nerve fibers due to absolute or relative elevations in intraocular pressure. Two types of glaucoma, open-angle and rubeotic, are reported to be more common in persons with diabetes.^{2,178}

There is conflicting information about the relationship between diabetes and open-angle glaucoma. Most reports describe a higher prevalence of ocular hypertension and open-angle glaucoma in diabetic than in nondiabetic persons. Additionally, patients with open-angle glaucoma or ocular hypertension are reported to have a higher prevalence of diabetes. Data from the 1976–1977 National Health Interview Survey indicate that diabetic persons 20 years of age or older (type unspecified) reported substantially higher rates of glaucoma than did the nondiabetic U.S. population.¹⁵⁸ In the Beaver Dam Eye Study, diabetes was associated with a modest increase in risk of definite and probable glaucoma.¹⁷⁸ Persons in the Framingham Eye Study with intraocular pressure greater than 20 mm Hg were 2–3 times as likely to have diabetes as others,¹⁷⁹ although other investigators have failed to find this relationship.¹⁸⁰

In the WESDR, the estimated 10-year incidence of glaucoma in the younger-onset group was 4%, in the older-onset group not taking insulin it was 7%, and in those taking insulin it was 12%. In older-onset persons, increasing duration of diabetes was associated with increased risk of glaucoma.¹⁸¹

It has been hypothesized that diabetic patients are at increased risk of optic nerve damage owing to vascular factors.¹⁷⁹ Because diabetic patients may be at increased risk of glaucoma, measurement of the intraocular pressure and ophthalmoscopic examination for changes of the cup-to-disk configuration and size is an important part of the ophthalmologic management of these patients. In patients who develop glaucoma, medical intervention is usually successful in preventing or retarding further field and visual loss.

Eyes with severe ischemic retinopathy or detachment of the retina, or eyes that have undergone vitrectomy, are at increased risk of developing rubeotic glaucoma.¹⁰ Abnormal new vessels on the iris and in the anterior chamber angle of the eye may lead to elevations of the intraocular pressure, severe optic nerve damage, and blindness with possible enucleation of the eye if it is painful. In some cases, panretinal photocoagulation may result in regression of the rubeotic vessels and control of the intraocular pressure. Other surgical (cyclocryotherapy and valve implants) or medical interventions (antiglaucoma medications, topical corticosteroids, and mydriatic cycloplegics) for rubeotic glaucoma are rarely successful in preserving vision.

Economic Costs of Blindness

The economic costs associated with blindness due to diabetes have been estimated. Chiang and associates¹⁸² reported that the cost to the federal government was \$12,769 for a "person-year" of blindness for a working-age American who becomes blind in adulthood; for those 65 years of age or older, it was \$823. These estimates did not include output loss, reduced productivity, societal burdens of rehabilitation, and other nonfederal expenses. Based on the WESDR estimates of prevalence of blindness in 5.8 million people with diagnosed diabetes in the United States in 1980 to 1982, it is estimated that the annual cost of blindness was \$500 million per year.

OPHTHALMOLOGIC MANAGEMENT

Health Care Delivery

Because it is possible in many cases to prevent visual loss with photocoagulation, and because proliferative retinopathy and clinically significant macular edema may be present before they affect vision, it is important to identify those diabetic persons in need of ophthalmologic evaluation.¹⁸³ The need for careful examination by ophthalmologists has been documented by Sussman and coworkers.¹⁸⁴ They found that internists, diabetologists, and senior medical residents correctly diagnosed the presence of proliferative retinopathy in only 49% of patients they examined (under optimal conditions), whereas ophthalmologists and retinal specialists correctly diagnosed its presence in 96% of cases.

Guidelines have been developed and implemented that suggest that all diabetic patients be informed of the possible ocular complications and of the role of the ophthalmologist in the management (detection and prevention) of these complications (Table 41-11).¹⁸⁵ Because it is rare for young (prepubertal) insulin-dependent patients to develop serious vision-threatening retinopathy during the first 5 years of diabetes,^{76,103,104} frequent examinations by an ophthalmologist need not begin until 5 years after diagnosis of diabetes. For older-onset individuals, because the age of onset of dia-

betes is frequently uncertain and there is a higher frequency of vision-threatening retinopathy at the time of diagnosis,^{17,115} regular periodic examinations by an ophthalmologist should begin shortly after diagnosis. Patients who are in poor glycemic control, are pregnant, or who have microalbuminuria or gross proteinuria should be examined by ophthalmologists, as they may be at higher risk for progression of retinopathy.

Recent data suggest that diabetic patients may not be receiving adequate ophthalmologic care.¹⁸⁶⁻¹⁸⁹ In the 1989 National Health Interview Survey, participants 18 years of age or older were asked if they had had a dilated eye examination in the past year.¹⁸⁸ Only 49% reported a dilated eye examination within a year of the interview. People with T2DM were more likely to have had a dilated eye examination if they were older, had a higher socioeconomic status, and had attended a diabetes education class. Receiving a dilated eye examination was not related to race, duration of diabetes, frequency of physician visits for diabetes, or health insurance in that study. Kraft and colleagues¹⁸⁹ identified and surveyed all primary care physicians in Indiana using a questionnaire. Of those surveyed, 1058 (70%) completed the eye care-related questions. The investigators reported that 52% of physicians performed in-office ophthalmoscopy, of which 90% were done through undilated pupils. In addition, nearly 58% of physicians reported that they referred all of their patients with T1DM and 40% reported they referred all of their patients with T2DM to eye care specialists. Physicians who had graduated earlier and those who were either general or family practitioners were less likely to refer their patients to eye care specialists.

In the WESDR in 1980-1982, only 63% of younger-onset and 50% of older-onset diabetic persons had seen an ophthalmologist within the previous 2 years before the examination; 25% of younger- and 36% of older-onset persons had never had an ophthalmologic examination.¹⁸⁶ It was estimated that in 1980-1982 there were 35,000 diabetic Americans with eyes with proliferative retinopathy with high-risk characteristics for severe visual loss and 230,000 with eyes with clinically significant macular edema that were untreated with photocoagulation.

There are a number of possible reasons that explain the high rate of patients with serious retinopathy who are not under the care of an ophthalmologist or who have not received photocoagulation treatment.¹⁸⁶ Physician-related factors include poor ophthalmoscopy skills, ophthalmoscopy through an undilated pupil, lack of knowledge about the benefits of photocoagulation treatment, and no or inadequate referral to ophthalmologists. In addition, there are a number of patient-related factors that explain failure to receive ophthalmologic care. These include the asymptomatic nature of vision-threatening retinopathy, a lack of knowledge about the benefits of timely detection by dilated eye examination and treatment with photocoagulation, lack of motivation or denial, an inability to pay for ophthalmologic care, a lack of time to go for such care, and a lack of availability or accessibility of ophthalmologic care. Findings from the WESDR showed that in persons with 10 or more years of diabetes, in those not having a dilated eye examination in the previous year "79% and 71% of those with Type 1 and Type 2, respectively, reported not having had one because they had no problems with their eyes, and 31% and 35% reported not having been told they needed one. Thirty-two percent and 11% said they were too busy, and 30% and 12% said they could not afford an examination." Persons with T1DM or T2DM were less likely to have had an eye examination if they did not have health insurance that covered such an examination.¹⁹⁰

TABLE 41-11. Recommendations for Eye Case for Diabetic Patients

PRIMARY-CARE PHYSICIAN INFORMS PATIENT AT TIME OF DIAGNOSIS OF DIABETES THAT:

Ocular complications are associated with diabetes and may threaten sight
Glycemic and blood pressure control reduces risk of developing retinopathy

Timely detection and treatment of retinopathy may reduce the risk of decreased vision

REFERRAL TO AN EYE DOCTOR COMPETENT IN OPHTHALMOSCOPY:

All patients 10-30 years of age who have ≥ 5 years of diabetes
All diabetic patients diagnosed after 30 years of age at the time of diagnosis or shortly thereafter

REFERRAL TO AN OPHTHALMOLOGIST:

All women with type 1 diabetes mellitus planning pregnancy within 12 months, in the first trimester, and thereafter at the discretion of the ophthalmologist

Patients found to have reduced corrected visual acuity, elevated intraocular pressure, and any other vision-threatening ocular abnormalities

A series of studies by Dasbach and colleagues¹⁹¹ and Javitt and associates¹⁹² in the U.S., and Crijns¹⁹³ in the Netherlands, have demonstrated that screening for diabetic retinopathy and obtaining ophthalmologic care results in significant savings in people with younger-onset diabetes. The analyses by Javitt and coworkers¹⁹² predicted an annual savings of an estimated \$240.5 million and 138,390 person-years of sight at a 60% screening and treatment rate implementation level. The study by Dasbach and coworkers¹⁹¹ also found that targeting the younger-onset cohort and the older-onset cohort taking insulin could achieve cost savings.

Screening programs for diabetic eye disease have thus been suggested to reduce blindness due to this disease.^{185,192} Other programs involve education. One such program, the National Eye Health Education Program (NEHEP), has been developed by the National Eye Institute. It is directed at patients with diabetes.¹⁹⁴ Its primary aim is to educate diabetic patients and their families regarding the need for dilated eye examinations. It is hoped that the program will lead to a change in behavior regarding pursuing eye care. However, while it has the potential to have an important impact, there is also a need to develop approaches designed to deal with the inability of some patients without health insurance to pay for ophthalmologic care.

Ophthalmologic Care

At each visit,¹⁹⁵ the ophthalmologic examination may include refraction and measurement of the visual acuity, measurement of the intraocular pressure, dilation of the pupil, and examination of the lens by slit-lamp biomicroscopy. Retinal edema is more easily detected using slit-lamp biomicroscopy and a corneal contact lens to provide a magnified stereoscopic view of the retina. Sketches of the retina and color stereoscopic fundus photographs should be obtained to document the presence and severity of the retinopathy. Photographs are used to accurately document the progression of retinal disease. Fluorescein angiography is used when focal photocoagulation treatment is considered and when the extent of retinal ischemia needs to be assessed. The angiograms demonstrate abnormal leakage from retinal blood vessels, which may be responsible for macular edema and may also demonstrate closure of small capillaries or arterioles. More highly specialized procedures, for example, vitreous fluorophotometry, macular recovery time measured with nyctometry, and electrophysiologic testing, are used largely as experimental tools to indicate retinal functional or physiologic abnormalities due to diabetes before the appearance of retinopathy.

REHABILITATION

The visual impairment in diabetes may range from minimal changes in color vision to total blindness and may include periods of rapid or slow progression with fluctuations in vision due to recurrent vitreous hemorrhage or macular edema. The unique problems confronted by visually impaired insulin-taking diabetic patients include identification of the type of insulin, determination of the amount of insulin in the vial, measurement of dose, and location of injection sites. Monitoring glucose levels using blood test strips and foot care become more difficult or impossible for the visually impaired diabetic patient. A number of low-vision aids, devices for insulin administration, and aids in glucose monitoring are available for the visually impaired diabetic patient.¹⁹⁶ Depending

on the degree of visual impairment, supportive rehabilitation services, including low-vision clinics, state vocational rehabilitation centers, and schools for the blind, are available. Social worker psychologists, orientation and mobility instructors, and rehabilitation teachers working as a team are needed to develop successful programs. They must help in handling the anxiety, anger, guilt, depression, loss of self-esteem, and difficulties in social adjustment suffered by the diabetic patients with visual loss.^{197,198} Other current or potential systemic problems must be taken into account when planning the program. Helping the patient accept the partial or complete visual loss is an essential step in planning living arrangements and in developing coping strategies.

Acknowledgments. The author acknowledges the support of grant EY03083 from the National Eye Institute. He thanks Dr. Barbara E.K. Klein and Mr. Scot Moss for reviewing the manuscript, Gene Knutson and Michael Neider for preparing the photograph, and Colleen Comeau for secretarial assistance.

Pathophysiology of Renal Complications

Maria Luiza Avancini Caramori

Michael Mauer

Diabetic nephropathy (DN) is the single most common disorder leading to renal failure in adults.¹ The annual cost of caring for these patients in the United States alone exceeds \$6 billion. Forty-four percent of patients entering end-stage renal disease (ESRD) programs in the U.S. are diabetic, most of whom (80% or more) have type 2 diabetes mellitus (T2DM).¹ DN develops in about 25–35% of patients with type 1 diabetic mellitus (T1DM), with a peak in the incidence after about around 15–20 years of disease.² Studies in T2DM patients from western Europe³ and in Pima Indians from Arizona⁴ show nephropathy rates similar to or higher than those of T1DM patients. The much higher prevalence of T2DM accounts in part for the greater contribution of these patients to incidence of ESRD. Once overt DN, as manifested as proteinuria, is present, ESRD can be postponed, but in most instances not prevented, by effective antihypertensive treatment^{5,6} or careful glycemic control.⁷ Moreover, there has been a rapid and continuous increase in the number of diabetic patients entering ESRD programs in the last decade.¹ Thus in the last 10–15 years, there has been intensive research into early predictors of DN risk, pathophysiologic mechanisms of diabetic renal injury, and early intervention strategies. This chapter discusses the current knowledge of the pathology and pathophysiology of DN.

Pathology

T1DM

The changes in kidney structure caused by diabetes are specific, creating a pattern not seen in any other renal disease. The severity of the diabetic lesions is related to diabetes duration, degree of glycemic control, and genetic factors. Ultimately, renal dysfunction results from these progressive structural changes. However, the relationship between duration of T1DM and extent of glomerular pathology is not precise. This is consonant with the marked variability in susceptibility to DN such that some patients may be in renal failure after having diabetes for 15 years or less while others escape complications despite having T1DM for many decades.

Light Microscopy

The earliest renal structural change in T1DM, renal hypertrophy, is not reflected in any specific changes detectable under light microscopy. In many patients, glomerular structure remains normal or near normal despite decades of diabetes.^{8–10} Others develop progressive diffuse mesangial expansion seen mainly as increased

periodic acid Schiff (PAS)-positive extracellular matrix (ECM) mesangial material (Fig. 42-1). In about 40–50% of patients developing proteinuria, there are areas of extreme mesangial expansion called Kimmelstiel-Wilson nodules or nodular mesangial expansion (Fig. 42-2). Mesangial cell nuclei in these nodules are palisaded around masses of mesangial matrix (MM) material with compression of surrounding capillary lumina. Nodules are thought to result from earlier glomerular capillary microaneurysm formation.¹¹ Although Kimmelstiel-Wilson nodules are diagnostic of DN, they are not necessary for renal dysfunction to develop. Early changes often include arteriolar hyalinosis lesions involving replacement of the smooth muscle cells of afferent and efferent arterioles with PAS-positive waxy homogenous pink material. The severity of these lesions is directly related to the frequency of global glomerulosclerosis, perhaps as the result of glomerular ischemia. One may also detect, by light microscopy, glomerular basement membrane (GBM) and tubular basement membrane (TBM) thickening, although this is often easier seen by electron microscopy. Finally, usually later in the disease, there is advanced tubular atrophy and interstitial fibrosis, common to most chronic renal disorders.

Immunofluorescence Microscopy

Diabetes is characterized by increased linear GBM, TBM, and Bowman's capsule staining,¹² especially for IgG (mainly IgG₄) and albumin.¹³ This increased staining is removed only by strong acid conditions, consistent with strong ionic binding of these plasma proteins to GBM ECM constituents. The intensity of staining is not related to the severity of the underlying lesions.^{12,13} The immunofluorescence technician should not confuse these findings with antibasement membrane antibody disorders. Diabetic immunohistochemical ECM changes in mesangium, GBM, and TBM through much of the natural history of DN are primarily due to expansion of the intrinsic ECM components normally present at these sites, including type IV and VI collagens, laminin, and fibronectin.¹⁴ However, the exact nature of the accumulated ECM material is not yet known.^{15,16} Replacement of these ECM molecules by scar collagens is a very late event.

Electron Microscopy

Glomerular structure is probably normal at onset of diabetes and changes can be detected by morphometric measurements within 1.5–2.5 years after onset.¹⁷ However, since the normal range for glomerular structures, such as GBM width or mesangial

FIGURE 42-1. Light photomicrographs of glomeruli from (A) a normal control and from (B) a T1DM patient. Note the diffuse mesangial expansion and glomerular basement membrane and Bowman's capsule thickening in the diabetic glomerulus (periodic acid Schiff, $\times 400$).

FIGURE 42-2. Light photomicrographs of glomeruli in sequential kidney biopsies performed at baseline and after 5 and 10 years of follow-up in a longstanding normoalbuminuric T1DM patient with progressive mesangial expansion and renal function deterioration. A. Note the diffuse and nodular mesangial expansion and arteriolar hyalinosis in this glomerulus from this patient who was normotensive and normoalbuminuric at the time of this baseline biopsy, 21 years after diabetes onset. The glomerular filtration rate (GFR) was reduced to 74 mL/min/1.73 m² (periodic acid Schiff, $\times 400$). B. 5-Year follow-up biopsy showing worsening of the diffuse and nodular mesangial expansion and arteriolar hyalinosis in this now microalbuminuric patient with declining GFR (59 mL/min/1.73 m²) (periodic acid Schiff, $\times 400$). C. 10-Year follow-up biopsy showing more advanced diabetic glomerulopathy in this now proteinuric patient with further reduced GFR (29 mL/min/1.73 m²). Note also the multiple small glomerular probably efferent arterioles in the hilar region of this glomerulus (periodic acid Schiff, $\times 400$), and in the glomerulus in Fig. 42-2A. (Used with permission from Caramori et al.⁴⁴⁰)

fractional volume [Vv(Mes/glom)] is quite wide, it may take time for some individuals to progress from the normal to the abnormal range. Others develop lesions so rapidly as to result in overt DN in as little as 10 years. However, glomerular changes of longstanding diabetes are always discernible by direct comparison with measures from the patient's nondiabetic identical twin.¹⁸ Using morphometric techniques, the first measurable change is thickening of the GBM (Fig. 42-3).¹⁹ TBM thickening parallels GBM thickening.^{18,20} Increase in the relative area of the mesangium may become measurable by 4–5 years (Fig. 42-4). Vv(Mes/glom) increases from about 0.2 in the normal state to about 0.4 when proteinuria begins, and 0.6–0.8 in patients with a glomerular filtration rate (GFR) about 40–50% of normal. In the largest study performed so far,⁸ 66 nonproteinuric patients with T1DM duration of at least 10 years (mean of 21 years) were divided on the basis of their albumin excretion rate (AER) into 4 groups: group I, 33 normoalbuminuric patients (AER <15 μ g/min); group II, 11 low-level microalbuminuric patients (AER 15–30 μ g/min); group III, 13 microalbuminuric patients (AER 31–70 μ g/min); and group IV, 9 microalbuminuric patients (AER 71–150 μ g/min). Glomerular structural parameters were compared to 52 age- and gender-matched normal controls. All parameters of glomerulopathy were abnormal in the normoalbuminuric group, although approximately one-half of the patients fell into the normal range (Fig. 42-5). Note that in many of group I (normoalbuminuric) patients, Vv(Mes/glom), the structural parameter most closely related to renal functional disturbances in diabetes⁹ (see below), overlapped with patients in the microalbuminuric groups (groups III and IV), and in some instances approached levels regularly associated with overt DN. Note also that several of the normoalbuminuric patients (group I) with Vv(Mes/glom) above the normal range had reduced GFR, hypertension, or both (Fig. 42-5A). Evaluating patients with shorter diabetes duration (10.8 (7.5–19.2) years [median (range)]), Berg and associates²¹ found greater GBM width and MM fractional volume [Vv(MM/glom)] in 36 normoalbuminuric adolescents than in normal controls, but did not report an increase in Vv(Mes/glom). Østerby, using pooled data from several studies from her laboratories,¹⁰ also described an increase in GBM width in normoalbuminuric T1DM patients with a mean diabetes duration of 12 years. Vv(Mes/glom) was similar in controls and normoalbuminuric patients in these studies and the different results are best explained by the marked differences in duration of diabetes in the normoalbuminuric patients.

FIGURE 42-3. Electron photomicrographs of GBM from normal control (A) and from T1DM patient (B) ($\times 11,000$). Note the thickening of the glomerular basement membrane in the diabetic patient.

FIGURE 42-4. Electron photomicrographs of mesangial area in normal control (A) and in T1DM patient (B) ($\times 3900$). Note the increase in mesangial matrix and cell content, the GBM thickening, and the decrease in the capillary luminal space in the diabetic patient.

There is, however, general consensus that on average, microalbuminuric patients have increased GBM width and $V_v(\text{Mes}/\text{glom})$ compared to normoalbuminuric patients^{8,22-24} and controls.^{8,23,24} However, all studies have shown wide ranges of glomerular structure among type 1 microalbuminuric patients. Thus GBM width ranges from the upper limits of normal to markedly increased. Moreover, there is no significant increase in GBM width (Fig. 42-5B) in patients with different levels of microalbuminuria.⁸ The same is true for $V_v(\text{Mes}/\text{glom})$ (Fig. 42-5A), where values in microalbuminuric patients in groups III and IV ranged from the upper limits of normal⁸ to levels which overlapped those of patients with proteinuria (unpublished observations). Patients in groups III and IV

had greater $V_v(\text{Mes}/\text{glom})$ values (Fig. 42-5A) than patients with lower levels of increased AER (15–30 $\mu\text{g}/\text{min}$; group II) or normoalbuminuric patients (group I), while group I and II overlapped completely.⁸ Østerby¹⁰ found some microalbuminuric patients with $V_v(\text{Mes}/\text{glom})$ in the normal range. This was also found to be true⁸ when patients with AER in the range of 15–30 $\mu\text{g}/\text{min}$ were examined (group II; Fig. 42-5A). However, at higher levels of microalbuminuria, $V_v(\text{Mes}/\text{glom})$ was increased in virtually all patients. Also, we found that patients with AER above 30 $\mu\text{g}/\text{min}$ had a relatively high incidence of hypertension, decreased GFR ($<90 \text{ mL}/\text{min}/1.73 \text{ m}^2$), or both.⁸ Nonetheless, even among these patients, the range of $V_v(\text{Mes}/\text{glom})$ was quite wide, and the values in these

FIGURE 42-5. A. Mesangial fractional volume [$V_v(\text{Mes}/\text{glom})$] in the 4 groups of patients. Group I, normoalbuminuric; group II, AER 15–30 $\mu\text{g}/\text{min}$; group III, AER 31–70 $\mu\text{g}/\text{min}$; and group IV, AER 71–150 $\mu\text{g}/\text{min}$. The shaded area represents the mean ± 2 SD in a group of 52 age-matched normal control subjects. Normal BP and GFR (solid circles); reduced GFR ($<90 \text{ mL}/\text{min}/1.73 \text{ m}^2$; open circles); hypertension ($\geq 140/85$; open squares); and reduced GFR and hypertension (circle within square). $*p < 0.005$ versus groups I and II. B. GBM width in the 4 groups of patients. The shaded area represents the mean ± 2 SD in a group of 52 age-matched normal control subjects. Normal BP and GFR (solid circles); reduced GFR ($<90 \text{ mL}/\text{min}/1.73 \text{ m}^2$; open circles); hypertension ($\geq 140/85$; open squares); and reduced GFR and hypertension (circle within square). $*p < 0.005$ versus groups I and II. (Both A and B reprinted with permission from Fioretto et al.⁸)

microalbuminuric patients overlapped with those of normoalbuminuric patients (Fig. 42-5A). The presence of serious diabetic glomerular lesions in some normoalbuminuric patients suggests that altered glomerular permeability to proteins is not a necessary precondition for the development of these lesions. Moreover, it is unlikely that established diabetic glomerular lesions are of little prognostic value in normoalbuminuric patients. On the contrary, preliminary studies indicate a greater risk of progression in normoalbuminuric patients with more advanced lesions.²⁵

Qualitative and quantitative changes in the renal interstitium, the extravascular intertubular compartment with its cellular elements and extracellular substances and spaces, are observed in patients with various renal diseases. Interstitial fibrosis is characterized by an increase in ECM proteins and cellularity.²⁶ Preliminary studies suggest that the pathogenesis of interstitial changes in DN is different from the MM, GBM, and TBM changes. Initial observations indicate that for all but the later stages of the disease, GBM, TBM, and MM changes represent the accumulation of basement membrane ECM material, while early on, interstitium expansion is largely due to cellular alterations. Only later, when GFR is already compromised, is interstitial expansion associated with increased interstitium fibrillar collagen and peritubular capillary loss.²⁷ Thus currently available data support the concept that interstitial changes are late contributors to the progressive decline in GFR that follows the initial development of serious glomerular and vascular DN lesions. These conclusions emanate from the following preliminary observations: cortical interstitial composition in patients with T1DM with mild interstitial expansion [cortical interstitial fractional volume [Vv(Int/cortex)] of ≈ 1.5 times normal] demonstrates a relative increase in the cellular component of interstitium, while a relative increase in collagen fibrils is seen only when Vv(Int/cortex) is about twice normal and patients already have decreased GFR.²⁷ This is in contrast to early mesangial expansion, where increased mesangial matrix fractional volume [Vv(MM/glom)] dominates.²⁸ Studies²⁰ also show that early GBM, TBM, and mesangial changes are correlated to glycemia, while early interstitial changes are not. These differences between glomerular and interstitial changes in T1DM patients may reflect different pathogenetic processes.

T2DM

The rate of development of DN lesions is less clear in patients with type 2 compared with patients with type 1 diabetes, since with the exception of the Pima Indian studies,²⁹ duration is usually not precisely established in these patients. Nonetheless, GBM width and Vv(Mes/glom) are increased in long-term normoalbuminuric Caucasian,³⁰ Japanese,³¹ and Pima Indian²⁹ T2DM patients. As in T1DM patients, there is considerable overlap with normal controls, and some normoalbuminuric T2DM patients have relatively advanced glomerular lesions.^{30,31} Thus, as is true for T1DM patients, there is a structural basis for explaining the progression to microalbuminuria and proteinuria among some normoalbuminuric T2DM patients. Whether normoalbuminuric T2DM patients with more advanced diabetic renal lesions are at greater risk of progression needs to be determined. In Pima Indians, glomerular structure was no different in microalbuminuric compared with normoalbuminuric patients with long duration, while microalbuminuric patients had more advanced glomerulopathy than normoalbuminuric patients with short duration. These results might explain the observation that some long-term normoalbuminuric patients are at high risk of progression. Further, as discussed below, there are more

varied renal structural patterns and patterns of functional progression among microalbuminuric, and perhaps proteinuric, patients with type 2 as compared with patients with type 1 diabetes, and the ultimate clinical course of these patients remains to be fully described.

A light microscopy study of 34 unselected microalbuminuric T2DM patients found that 10 (29.4%) had normal or near normal renal structure,³² a finding uncommon in T1DM. Ten patients had renal structural changes typical of those seen in type 1 diabetic patients with more or less balanced severity of glomerular, tubulointerstitial, vascular, and global glomerulosclerosis lesions. However, 14 (41.2%) had atypical patterns of renal injury with absent or only mild diabetic glomerular changes associated with other disproportionately severe renal structural changes, including important tubulointerstitial lesions with or without arteriolar hyalinosis and with or without increased global glomerular sclerosis. Patients with proliferative retinopathy all had typical and well-established DN lesions. None of the patients without retinopathy had typical lesions. However, background retinopathy could be associated with any of the three structural categories defined above. These studies were confirmed by electron microscopy observations,³⁰ showing that microalbuminuric T2DM patients more frequently had electron microscopy morphometric glomerular structural measures in the normal range and, as a group, had less severe lesions than microalbuminuric T1DM patients. Many of these observations have been confirmed in Japanese type 2 diabetic patients.³¹ On the other hand, Pima Indian type 2 diabetic patients, who are known to be at very high risk of ESRD, appear to have lesions more similar to those seen in type 1 diabetic patients.³³ Also, proteinuric type 2 diabetic patients had electron microscopy appearances consistent with typical diabetic glomerulopathy, with an increase in Vv(Mes/glom) and Vv(MM/glom) together with GBM thickening.³⁴ Interstitial expansion was also observed when these patients were compared to nondiabetic controls.³⁴ Similar results were seen in an earlier study that included proteinuric type 2 Japanese diabetic patients.³⁵ Moreover, there are reports that type 2 diabetic patients have an increased incidence of nondiabetic lesions, such as proliferative glomerulonephritis and membranous nephropathy, but this is most likely because biopsies were done in atypical cases. When biopsies are performed for research purposes, the incidence of other definable renal diseases is very low (<5%).^{32,36}

It is currently unclear why some studies show more structural heterogeneity in type 2 than in type 1 diabetes^{30,31,36} while others do not.^{34,35} Whether this is due to differences in patient populations, or to other as yet unknown variables remains to be determined. However, this is an important question since the rate of progression towards ESRD in T2DM appears to be at least in part related to the severity of the classic changes of diabetic glomerulopathy (see below).

STRUCTURAL-FUNCTIONAL RELATIONSHIPS IN DIABETIC NEPHROPATHY

T1DM

Expansion of the mesangium, mainly due to ECM accumulation, is believed to ultimately reduce glomerular capillary luminal space, decreasing glomerular filtration surface and GFR. Vv(Mes/glom) is a good predictor of GFR in type 1 diabetic patients, and it is also related to AER levels and hypertension.⁹ The total peripheral capillary filtration surface per glomerulus [Sv(PGBM/glom)] is directly correlated with GFR (Fig. 42-6) and inversely correlated with the

FIGURE 42-6. Relationship between capillary filtration surface area per glomerulus and creatinine clearance ($r = 0.78$, $p < 0.001$). (Reproduced with permission from Ellis et al.⁴⁴)

degree of mesangial expansion (Fig. 42-7). The thickness of the GBM is directly related to AER, but increasing albuminuria appears to be related to increasing mesangial expansion (Fig. 42-8) and not to other structural changes.³⁷ Percentage of global glomerulosclerosis and interstitial expansion are also correlated with the clinical manifestations of DN (proteinuria, hypertension, and declining GFR). Progressive tubular atrophy, interstitial fibrosis, glomerular arteriolar hyalinosis, arteriosclerosis, and glomerulosclerosis are also important components of DN that probably contribute to the reduction in GFR independently from the glomerular lesions. Finally, larger-vessel atherosclerosis, perhaps especially in T2DM, may lead to ischemic renal tissue damage. In type 1 diabetic patients, these lesions tend to progress more or less in parallel, while in type 2 diabetic patients this is less often the case. As already mentioned, preliminary observations suggest that longstanding normoalbuminuric type 1 diabetic patients who progress to DN have more advanced glomerular lesions than pa-

FIGURE 42-7. Relationship of Vv(Mes/glom) expressed as percentage of total mesangium and S/V of the peripheral capillary surface or Sv(PGBM/glom) ($r = -0.86$, $p < 0.0005$). (Reproduced with permission from Mauer et al.⁹)

FIGURE 42-8. Correlation between the change in mesangium fractional volume [Vv(Mes/glom)] and the change in albumin excretion rate (AER) over 5 years ($r = 0.642$, $p < 0.05$). (Reproduced with permission from Fioretto et al.³⁷)

tients that remain normoalbuminuric after long-term follow-up.²⁵ In this preliminary 5- to 17-year follow-up study of normoalbuminuric patients with longstanding diabetes, patients progressing to microalbuminuria or proteinuria had worse glomerular lesions at baseline than those who remained normoalbuminuric, but these findings are as yet unconfirmed. In longitudinal studies of microalbuminuric type 1 diabetic patients Bangstad and colleagues³⁸ found that GBM width at baseline biopsy was predictive ($r^2 = 0.67$; $p < 0.0001$) of AER after 6 years of follow-up, whereas Vv(Mes/glom) was a significant but less precise predictor.

Changes in interstitium also correlate with functional changes, and interstitial expansion has generally been accepted as the best histologic correlate of renal function in glomerular diseases.³⁹ Studies have shown that both GFR and serum creatinine at the time of biopsy best correlate with Vv(Int/cortex), while the degree of renal dysfunction may not reflect the severity of glomerular pathology.⁴⁰ However, as discussed below, this may depend on how carefully glomerular pathology is measured. Thus, in 96 type 1 diabetic patients with GFR ranging from normal to 45 mL/min/1.73 m² (35 with reduced GFR) and AER from normal to proteinuria (34 with proteinuria), the correlation of Vv(Int/cortex) and Vv(Mes/glom) was only 0.38 ($p < 0.01$). Both Vv(Int/cortex) ($r = 0.49$, $p < 0.001$) and Vv(Mes/glom) ($r = 0.41$, $p < 0.001$) correlated inversely with GFR, and were additive in stepwise multiple regression analyses ($r = 0.55$, $p < 0.001$).⁴¹ In type 1 and type 2 diabetic patients with overt DN the rate of progression in interstitial fibrosis in the 4-year follow-up biopsy correlated with the rate of GFR decline.⁴² However, in type 1 diabetic patients at earlier stages of DN (normoalbuminuria and microalbuminuria), increasing AER correlated with increasing Vv(Mes/glom) in sequential biopsies performed 5 years apart, while Vv(Int/cortex) remained constant.³⁷ These studies support the view that structural-functional relationships in DN may change as the disease evolves.

T2DM

The structural-functional relationships are less clear in type 2 diabetes. Some studies show weaker structural-functional relationships^{30,31} while others reported more typical structural-functional

relationships in microalbuminuric and proteinuric type 2 diabetic patients.^{34,35} Vv(Mes/glom) and Vv(MM/glom) were correlated with GFR and proteinuria, while GBM width correlated only with proteinuria,^{34,35} in a fashion similar to type 1 diabetic patients.⁴¹ Also, as described in type 1 diabetic patients,⁴¹ multiple regression analysis found that GFR was related to both mesangial and interstitial lesions in type 2 diabetic patients.³⁴ One study argued that the underlying pattern of renal injury does not predict the rate of GFR decline among a Caucasian cohort of proteinuric type 2 diabetic patients.⁴³ In contrast, a large 4.3-year follow-up study of angiotensin converting enzyme (ACE) inhibitor-treated Caucasian microalbuminuric and proteinuric type 2 diabetic patients found that patients with more rapid GFR decline had greater Vv(Mes/glom) and GBM width at baseline.⁴⁴ Also, after 2 years of follow-up of microalbuminuric and proteinuric type 2 diabetic patients, all with typical glomerulopathy, increase in the Vv(Int/cortex) was correlated with changes in proteinuria over the same interval.⁴⁵ Thus, as suggested above, it is reasonable to conclude that glomerular lesions are key to the early functional changes of DN, while interstitial and vascular changes may become increasingly important in determining the rate of progression of the disease from established nephropathy to ESRD.

PATHOGENESIS OF DIABETIC NEPHROPATHY

Glycemic Control

Although important modulating factors may exist, DN is secondary to the long-term metabolic aberrations found in diabetes, and exposure to elevated glucose levels appears central to the expression of this disorder. Studies in T1DM and T2DM found that improved glycemic control could reduce the development of DN. The Diabetes Control and Complications Trial (DCCT) demonstrated that the risk of microalbuminuria in type 1 diabetic patients was decreased by strict glycemic control.⁴⁶ This study did not show an effect of improved glycemic control in the progression from microalbuminuria to proteinuria, although the study may have had limited power to demonstrate this. The beneficial effects of this 6.3 years of intensive treatment could still be observed 4 years after the end of the study.⁴⁷ The United Kingdom Prospective Diabetes Study (UKPDS) also demonstrated a decreased incidence of DN after 10 years of intensive glycemic control in recently diagnosed type 2 diabetic patients.⁴⁸ Moreover, a 5-year randomized clinical trial in 48 type 1 diabetic kidney transplant recipients demonstrated that the development of one of the earliest diabetic renal lesions, increased Vv(MM/glom), was prevented by strict glycemic control.⁴⁹ Also, intensive insulin treatment for 26–34 months decreased the rate of GBM thickening and increase in Vv(MM/Mes) and matrix star volume in a controlled trial in 18 microalbuminuric type 1 diabetic patients.⁵⁰ Finally, regression of established diabetic glomerular lesions has been demonstrated in the native kidneys of 8 type 1 diabetic patients with 10 years of normoglycemia induced by successful pancreas transplantation (Fig. 42-9 and Fig. 42-10).⁵¹ These studies strongly suggest that hyperglycemia is not only necessary for DN lesions to develop, but is also necessary to sustain established lesions. Alleviation of hyperglycemia allows reparative mechanisms to be expressed which ultimately result in healing of the original diabetic glomerular injuries. Studies evaluating the brain-type glucose transporter (GLUT-1) in animals reinforce the pathogenic role of glycemia on the development of DN. High glucose can increase GLUT-1 expression and glucose transport activ-

FIGURE 42-9. (A) Thickness of the glomerular basement membrane, (B) thickness of the tubular basement membrane, (C) mesangial fractional volume, and (D) mesangial matrix fractional volume at baseline and 5 and 10 years after pancreas transplantation. The shaded areas represent the normal ranges obtained in 66 age- and gender-matched controls (means $\pm$ 2 SD). Data for individual patients are connected by lines. (Reproduced with permission from Fioretto et al.⁵¹)

ity in rat mesangial cells.⁵² These effects are mediated by transforming growth factor- β (TGF- β).⁵³ Rat mesangial cells transduced with human GLUT-1 and overexpressing GLUT-1 protein showed increased glucose uptake and ECM synthesis, even in normal glucose concentration.⁵⁴ The mechanisms involved in the glomerular injury caused by hyperglycemia will be discussed in detail later.

Hemodynamic Mechanisms

Berkman and Rifkin⁵⁵ described a diabetic patient with unilateral renal artery stenosis and marked diabetic lesions in the kidney exposed both to hypertension and diabetes, while the contralateral kidney, protected from hypertension by the narrowed renal artery, had only ischemic changes. A model of unilateral renal artery stenosis in diabetic rats⁵⁶ seemed to confirm this human observation, although hypertensive and diabetic changes were not differentiated in this study. Insulin-treated diabetic rats have glomerular hyperfiltration explainable by increased single nephron GFR, which is due to increased single nephron blood flow and, in the Munich-Wistar rat strain, increased glomerular capillary pressure.⁵⁷ Thus alterations in intraglomerular hemodynamics could influence the rate at which diabetic lesions develop. Some studies reported that glomerular hyperfiltration was a risk factor for the development of microalbuminuria.^{58,59} However, there is still controversy as to whether increased GFR is a predictor of progression.^{60,61}

FIGURE 42-10. Photomicrographs of renal biopsy specimens obtained before and after pancreas transplantation in a 33-year-old woman with T1DM of 17 years' duration at the time of transplantation. Panel A shows a typical glomerulus from the baseline biopsy specimen, which is characterized by diffuse and nodular (Kimmelstiel-Wilson) diabetic glomerulopathy. Mesangial matrix expansion and the palisading of mesangial nuclei around the nodular lesions are evident. In panel B, a typical glomerulus 5 years after transplantation, shows the persistence of the diffuse and nodular lesions. Panel C shows a typical glomerulus 10 years after transplantation, with marked resolution of diffuse and nodular mesangial lesions and more open glomerular capillary lumina (periodic acid Schiff, $\times 120$). (Reproduced with permission from Fioretto et al.⁵¹)

Several mechanisms have been proposed as mediators of diabetes-induced hyperfiltration. Increased renal tissue and urinary kallikrein levels were associated with increased GFR and renal plasma flow in moderately hyperglycemic diabetic rats,⁶² and treatment with a bradykinin B2 receptor antagonist acutely reduced GFR and renal plasma flow in these animals.⁶³ Urinary kallikrein excretion was also increased in type 1 diabetic patients with glomerular hyperfiltration.⁶⁴ The intrarenal renin-angiotensin system within glomeruli and proximal tubules may be activated by hyperglycemia, leading to increased angiotensin II production, which may exert feedback inhibition of systemic renin release.^{65,66} Angiotensin II concentration is higher in the glomeruli than systemically.⁶⁷ ACE activity is reduced in the renal cortex but enhanced in glomeruli and vessels of diabetic rats⁶⁸ and patients,⁶⁹ suggesting that renal vessels and glomeruli may be regulated differently from the tubulointerstitial renin-angiotensin system. The genesis of glomerular hyperfiltration has also been associated with increased nitric oxide (NO) generation or action, by a glucose-dependent mechanism.^{70,71} The vasodilatation caused by increased NO could enhance the permeability to macromolecules, leading to albuminuria.⁷² Furthermore, recent data have shown enhanced NO synthesis by endothelial NO synthase (eNOS) in afferent arterioles and glomerular endothelial cells in diabetic rats, suggesting a pivotal role of NO in preferential afferent arteriolar dilatation, glomerular enlargement, and functional glomerular hyperfiltration in the early stages of DN.⁷³ Treatment with a nonselective NOS inhibitor normalized GFR and plasma renal flow levels in diabetic rats.⁷⁴ NO activity was shown to be increased in microalbuminuric versus normoalbuminuric type 1 diabetic patients or nondiabetic controls, and related to GFR and

AER.⁷⁵ Other studies suggest that hyperfiltration may result from an increased proximal tubular fluid reabsorption, and independent of any primary malfunction of the glomerular microvasculature.⁷⁶

However, one cannot explain the *genesis* of DN by hyperfiltration alone. Insulin-treated diabetic rats with hyperfiltration have slower development of diabetic renal lesions than untreated diabetic rats having worse hyperglycemia and relative hypofiltration; in fact, these markedly hyperfiltrating insulin-treated animals do not seem to develop mesangial expansion disproportionate to the size of the glomerulus.⁷⁷ Further, reduction in nephron mass in rats by uninephrectomy produces glomerular hemodynamic perturbations⁷⁸ that are similar to diabetes,⁵⁷ but does not produce the lesions⁷⁹ that are classic for DN in animals.^{80,81} The central lesion associated with hyperfiltration in rats, focal segmental glomerular sclerosis,⁸² is not an important lesion in human or animal diabetes (see the section on pathology). It has been suggested that reduced glomerular number at birth may be a risk factor for progressive renal disease and hypertension.⁸³ One study in type 2 diabetic patients suggested that reduced glomerular number was associated with increased DN risk.⁸⁴ However, studies in type 1 diabetic patients do not confirm these observations. Glomerular number estimated at autopsy was decreased in type 1 diabetic patients only if ESRD was present.⁸⁵ No differences in glomerular number were found between type 1 diabetic patients with established DN, but not ESRD, and controls.⁸⁵ Another study, evaluating 32 type 1 diabetic patients ranging from normoalbuminuria to proteinuria, and serum creatinine ≤ 1.5 mg/dL, corroborated these findings.⁸⁶ Glomerular number, estimated by morphometric techniques in kidney biopsy tissue, did not correlate with functional or structural

parameters.⁸⁶ Also, reduced nephron mass, such as in patients with uninephrectomy, has not been documented to produce DN lesions in humans. Moreover, DN lesions may not develop faster in type 1 diabetic kidney transplant recipients (single-kidney diabetic patients) than in type 1 diabetic patients with their native kidneys, matched for diabetes duration.⁸⁷ These studies suggest that glomerular number is probably not a crucial variable in the development of DN, although it may be important in progression once clinical findings of DN are present.

Lowering glomerular capillary pressure by long-term ACE inhibitor therapy prevented the development of focal segmental glomerular sclerosis,⁸⁸ but did not prevent the GBM widening and increase in Vv(Mes/glom) that occurs in the first 6 months of diabetes in rats.⁸⁹ Thus, renin-angiotensin system blockage may not prevent the *development* of specific early DN lesions in diabetic animals⁸⁹ and this has not been tested in human diabetes. On the other hand, there are studies which suggest that renin-angiotensin system blockage may slow the rate of progression of established DN lesions and clinical progression in humans. The influences of renin-angiotensin system blockage on clinical progression of DN are discussed in Chap. 43. Here it is of interest to note that ACE inhibitor therapy prevented an increase of GBM width and perhaps changed Mes composition, but had no effect on Vv(Mes/glom), in microalbuminuric type 1 diabetic patients with established diabetic lesions.⁹⁰ Cortical interstitial expansion was also prevented in type 1⁹¹ and type 2⁴⁵ diabetic patients with already-increased AER. These effects may not be specific to ACE inhibition, as β -blocker therapy in these studies showed similar effects on blood pressure and lesions.^{90,91} Taken together these studies could support the hypothesis that hemodynamic abnormalities may be more important in influencing the *progression* of established DN lesions than in serving as the genesis of these structural changes. Thus, occlusion of glomerular capillaries or restriction of filtration surface within nonsclerosed glomeruli, as a consequence of advanced diabetic renal lesions, could cause compensatory enlargement of remaining glomeruli associated with increased intraglomerular pressures and flows and permselectivity alterations.⁸² Such abnormal hemodynamic forces could accelerate disruption of the residual glomeruli, thus contributing to a destructive cycle that promotes progressive tissue injury and loss of renal function.^{82,92}

Although we are arguing that a case has not been made that currently allows acceptance of the hypothesis that hemodynamic abnormalities are responsible for the *genesis* of the early lesions of DN, it is nonetheless possible that manipulations which can affect glomerular hemodynamics might also affect the development of early diabetic renal lesions through other than hemodynamic influences. For example, the renin-angiotensin system could mediate renal growth responses and renal ECM production and turnover. Angiotensin II stimulates *in vitro* mesangial cell proliferation and fibronectin synthesis.⁹³ Also, the glucose-stimulated increase in mesangial cell collagen production could be blocked by enalapril.⁹⁴ Further, increased glomerular mRNA expression for ECM components including α_1 chains of type I [$\alpha_1(I)$], III [$\alpha_1(III)$], and IV [$\alpha_1(IV)$] collagens, and laminin β_1 were attenuated by ACE inhibitor therapy in streptozocin diabetic rats.⁹⁵ Captopril inhibits the 72-kd and 92-kd matrix metalloproteinases (MMP-2 and MMP-9, respectively), two distinct type IV collagenases,⁹⁶ thus favoring ECM accumulation. However, lisinopril, a nonsulphydryl ACE inhibitor, inhibited these MMPs only at concen-

trations 100 times those of captopril.⁹⁶ Further, zinc could reverse the inhibitory effect of captopril on metalloproteinases, arguing against a renin-angiotensin system-dependent effect.⁹⁶ Thus drugs affecting the renin-angiotensin system might also impact ECM dynamics and thereby renal structure in diabetes. However, the mechanisms of action of these agents appear complex, are incompletely understood, and may in part be independent of the renin-angiotensin system. TGF- β expression may also be regulated in parallel with renin.^{97,98} Thus increased juxtaglomerular apparatus prorenin production may be associated with other increased juxtaglomerular apparatus activities such as TGF- β production, and the latter has been linked to glomerular ECM abnormalities in diabetes⁹⁹ (see below). Thus glomerular hyperfiltration could promote ECM accumulation by increases in the expression of TGF- β , and this might be modeled *in vitro* by the mechanical stretching of mesangial cells.¹⁰⁰

Genetics

Genetic predisposition appears to be the most important determinant of DN risk in both T1DM and T2DM. Differences in the prevalence of DN in different patient populations support this view.^{1,101,102} Moreover, only about one-half of patients with poor glycemic control develop DN,¹⁰³ while some patients do so despite relatively good control, findings consistent with genetically modulated risk.

Familial Clustering of Diabetic Nephropathy

Since the first report about 10 years ago,¹⁰⁴ genetic predisposition to DN has been suggested in multiple cross-sectional studies in type 1^{105,106} and type 2^{107–110} siblings concordant for diabetes. There is a large difference (300–800%) in the cumulative risk of DN between siblings of probands with or without DN, and some of the data are consonant with a major gene effect, with an autosomal dominant mode of inheritance.¹⁰⁶

Familial Studies of Blood Pressure, Cardiovascular Disease, and Diabetic Nephropathy

An association between DN and predisposition to hypertension and cardiovascular disease has also been suggested by some,^{111–116} but not all¹¹⁷ studies. Higher blood pressure values were observed in parents of proteinuric patients with T1DM,¹¹¹ while a higher prevalence of hypertension has been described in parents of proteinuric and microalbuminuric type 1 diabetic patients.^{112,113} Diabetic patients with advanced nephropathy also had higher mean arterial blood pressures during adolescence.¹¹³ Prediabetic blood pressure levels predicted AER after diabetes onset,¹¹⁴ and presence of hypertension in both parents increased the risk of proteinuria¹¹⁵ in type 2 diabetic Pima Indians. The prevalence of cardiovascular disease and cardiovascular death was found to be significantly greater in the parents of type 1 diabetic patients with nephropathy,¹¹⁶ and a positive family history of cardiovascular disease was more frequent in those DN patients who had suffered a cardiovascular event. This study indicates that familial predisposition to cardiovascular disease increases both the risk of nephropathy and the risk of cardiovascular disease in type 1 diabetic patients with nephropathy, linking the pathogenesis of DN to factors also favoring the development of atherosclerosis.^{111,112,118} Recent data also

suggest that AER and blood pressure are heritable and linked in Caucasian families with T2DM.¹¹⁹

Sodium/Lithium Countertransport

Sodium/lithium (Na^+/Li^+) countertransport activity is genetically determined, and has been suggested to be related to hypertension and cardiovascular disease in nondiabetic subjects.¹²⁰ Increased Na^+/Li^+ countertransport activity has been reported in diabetic patients with microalbuminuria or overt DN by some^{112,121,122} but not all¹²³ authors, albeit the later study was in type 2 diabetic patients. Increased Na^+/Li^+ countertransport activity has been described in a study of parents of proteinuric type 1 diabetic patients,¹²⁴ although not in another.¹¹⁷ Na^+/Li^+ countertransport activity was similar in 44 identical twin pairs discordant for T1DM,¹²⁵ and both values were higher than those of 44 age-matched nondiabetic controls. Interestingly, systolic blood pressure was higher in the diabetic twins, but nondiabetic twins and controls had similar blood pressure values. These findings suggest that raised erythrocyte Na^+/Li^+ countertransport activity seems to be inherited rather than a consequence of diabetes.¹²⁵ Raised erythrocyte Na^+/Li^+ countertransport activity was associated with a fourfold increased risk of development of persistent microalbuminuria in type 1 diabetic patients.¹²⁶

Na^+/Li^+ countertransport has parallels with the Na^+/H^+ antiport exchange system that is involved in the regulation of intracellular pH, cell volume and growth, and proximal tubular sodium reabsorption.¹²⁷ There is increased Na^+/H^+ antiport activity in leukocytes¹²⁸ and cultured skin fibroblasts^{129,130} of type 1 and type 2 diabetic patients with microalbuminuria and clinical proteinuria. Also, since cultured skin fibroblast Na^+/H^+ antiport activity is highly correlated among siblings concordant for T1DM and for nephropathy lesions,¹³¹ and independent of environmental factors, it was suggested that these cultured skin fibroblast abnormalities are genetically regulated.

Diabetic Nephropathy Genes

There are ongoing searches for genetic loci related to DN susceptibility through genomic scanning and through candidate gene approaches. Neither approach has yet yielded definitive results, but indications are that multiple genes may be involved.^{132,133} Segregation analyses in Pima Indians suggests that a major gene effect with a relatively frequent disease allele is the mode of inheritance of DN in type 2 diabetic patients.¹³⁴ Sib-pair linkage analysis in families of type 2 diabetic Pima Indians showed some evidence for linkage with DN in 4 chromosomal regions (chromosomes 3, 7, 9, and 20), the strongest one in chromosome 7.¹³⁵ Previous studies in the Caucasian population have shown linkage between DN and chromosome 7q in type 2 diabetic patients¹³⁶ and chromosome 3q in type 1 diabetic patients.¹³⁷ Recent results of segregation analysis in Caucasian type 2 diabetic families also suggest a major gene effect for AER.¹³⁸ Several genes have been proposed as plausible candidates based upon the pathophysiology of DN. Genetic polymorphism affecting background vascular risk in the general population, such as the genes related to the renin-angiotensin system, have been evaluated in many studies in diabetic patients. Polymorphism in the ACE gene, consisting of an insertion or deletion (I/D) of a 287-base pair sequence has also been associated with rate of GFR decline in nondiabetic renal diseases.¹³⁹ It is still not clear if ACE polymorphism is important in the *genesis* of DN,^{140–144} although a more recent follow-up study supports that this is so.¹⁴⁵

There is, however, growing evidence that ACE polymorphism can be important in DN progression and response to ACE inhibitor therapy.^{146–148} In normo- and microalbuminuric type 1 diabetic patients, AER appears to increase faster in patients with the II genotype,¹⁴⁸ however these patients appear to have the best response to ACE inhibitor therapy.^{147,148} On the other hand, D was the risk allele for development of DN in Caucasian type 1 diabetic patients followed for 6 years.¹⁴⁵ Also, the DD genotype was more frequent in normoalbuminuric or microalbuminuric Japanese type 2 diabetic patients who doubled AER or changed AER class (progressors), than in patients who had not progressed after 10 years of follow-up.¹⁴⁶ Despite progression not being associated with ACE genotype in Caucasian normoalbuminuric or microalbuminuric type 2 diabetic patients,¹⁴⁹ patients with II genotype ($n = 11$) did not decrease GFR after 9 years of follow-up. Moreover, presence of the D allele in Caucasian type 2 diabetic patients was related to the presence of more severe DN lesions.¹⁵⁰ Other studies did not find associations between ACE gene polymorphism and DN^{133,151–157} or rate of GFR decline¹⁵⁸ in type 1 or type 2 diabetic patients. One meta-analysis concluded that the D allele was significantly associated with DN in a dominant model (DD + ID versus II) in both type 1 and type 2 diabetic patients.¹⁵⁹ Another one found this association to be significant only in Japanese type 2 diabetic patients, but not in Caucasian type 1 or type 2 diabetic patients.¹⁶⁰ Different definitions of DN patients, different ascertainment strategies, real genetic differences among these populations, or selection bias could have accounted for the different results.

Association with DN risk in type 1 or type 2 diabetic patients and polymorphisms in the angiotensinogen gene was found in some^{161,162} but not in all^{156,157,163,164} studies. One study observed association between the T-allele angiotensinogen gene and elevated AER only when interaction with the D-allele of the ACE I/D polymorphism was considered.¹⁶⁵ Interaction between ACE and angiotensinogen gene polymorphism has been previously described in cross-sectional¹⁴⁰ but not confirmed in longitudinal¹⁴⁵ studies. A meta-analysis did not find association between angiotensinogen gene polymorphism and DN.¹⁶⁶

Two large studies did not find a role for angiotensin II type 1 receptor polymorphism in DN,^{167,168} while another found this polymorphism to significantly contribute to DN risk in type 1 diabetic patients only when accompanied by poor glycemic control.¹⁶⁹

Associations with DN risk have also been reported for polymorphisms in the human inducible NOS (iNOS),¹⁷⁰ PC-1,¹⁷¹ heparan sulfate proteoglycan,¹⁷² paraoxonase 2,¹⁷³ MMP-9,¹⁷⁴ TGF- β_1 ,¹⁷⁵ protein kinase C (PKC β),¹⁷⁶ and haptoglobin¹⁷⁷ genes. Studies of polymorphisms in eNOS,^{178–180} aldose reductase,^{181–183} plasminogen activator inhibitor-1,^{154,184} interleukin-1,^{185,186} apolipoprotein E,^{187–190} GLUT-1,^{191,192} and methylenetetrahydrofolate reductase^{193,194} genes showed conflicting results.

Other genes studied include hepatocyte nuclear factor 1 α ,¹⁹⁵ renin,¹⁹⁶ atrial natriuretic peptide,¹⁹⁷ α_1 (IV) collagen,¹⁹⁸ interleukin-1 receptor antagonist,¹⁹⁹ G protein,²⁰⁰ β_3 -adrenergic receptor,²⁰¹ decorin,¹⁵⁴ Werner syndrome helicase,¹⁵⁴ kallikrein,²⁰² bradykinin B1-²⁰³ and B2-²⁰⁴ receptors, paraoxonase 1,^{205,206} and insulin.²⁰⁷

Thus the genetic determinants of DN risk are still not fully understood. However, it is reasonable to hypothesize that a single gene with a major effect or several genes with moderate or small effects interacting with the metabolic abnormalities of diabetes may be responsible for the genetic susceptibility to DN. Further

research in this area is likely to lead to important new information regarding risk factors, pathogenesis, and treatment of DN.

PATHOPHYSIOLOGY OF DIABETIC NEPHROPATHY

The renal lesions of DN are mainly due to accumulation of ECM components, such as collagens, tenascin, and fibronectin,¹⁴ as well as other as yet undescribed molecules. ECM accumulation occurs early in the GBM¹⁹ and TBM,²⁰ is the principal cause of mesangial expansion, and also contributes to the later stages of interstitial expansion.²⁷ This ECM accumulation is clearly secondary to an imbalance between synthesis and degradation of ECM components. However, not all renal ECM components change in parallel in DN. Thus, $\alpha_3(\text{IV})$ and $\alpha_4(\text{IV})$ chains persist or increase in density in the GBM of patients developing diabetic renal lesions, while $\alpha_1(\text{IV})$ and $\alpha_2(\text{IV})$ chains are decreasing in density in the peripheral capillary wall and MM in patients with rapid development of DN lesions, but remain unchanged in patients with slow development of DN lesions despite longstanding T1DM.^{15,208} Thus the ECM changes in diabetes are highly site-specific, differing in direction in the GBM compared to MM, and suggesting that variables related to cell type (e.g., glomerular epithelial cell for GBM, mesangial cell for MM) are important determinants in the response to the diabetic state. Moreover, these patterns of cell response may be genetically regulated. Type VI collagen, the other major glomerular collagen, is decreased in density of distribution in the endothelial aspect of the GBM and in MM in patients with both slow and fast development of DN lesions, albeit with greater reduction in the latter.¹⁶ Thus the exact ECM component responsible for MM expansion in DN remains to be described.

Mesangial cells cultured in high glucose concentration accumulate various matrix components.^{209,210} Matrix metalloproteinases (MMPs) have been implicated in the abnormal *in vitro* degradation of MM by these cells.²¹¹ MMP activity is regulated at several levels, including gene expression, extracellular activation, and inhibition by specific tissue inhibitors of MMPs (TIMPs). MMPs and TIMPs can be modulated by protein kinase C (PKC) agonists, such as cytokines and hormones, and growth factors such as TGF- β .^{212–215}

The major hypotheses as to how hyperglycemia causes DN are: (1) increased activity of a variety of growth factors, including TGF- β , growth hormone (GH), insulin-like growth factor (IGF), vascular endothelial growth factor (VEGF), and epidermal growth factor (EGF); (2) activation of PKC isoforms; (3) activation of cytokines, including renin, angiotensin, endothelin, and bradykinin; (4) formation of reactive oxygen species; (5) increased formation of glycation products; (6) increased activity of the aldose reductase pathway, and (7) decreased glycosaminoglycan content in basement membranes ("Steno hypothesis"). The various hypotheses overlap and intersect with one another. Polyol pathway-induced redox changes or hyperglycemia-induced formation of reactive oxygen species could potentially account for most of the other biochemical abnormalities.^{216,217} These mechanisms, reviewed below, could be influenced by genetic determinants of susceptibility or resistance to hyperglycemic damage.

Growth Factors

This subject has recently been reviewed in detail by Flyvbjerg²¹⁸ and Chiarelli and colleagues²¹⁹ and, using a similar organizational scheme, it is summarized here.

TGF- β

TGF- β isoforms (TGF- β_1 , TGF- β_2 , and TGF- β_3), mRNA, and proteins and TGF- β -receptor mRNA have been demonstrated in all glomerular and proximal tubular cells.^{220,221} Glomerular mesangial and epithelial cells exposed *in vitro* to TGF- β demonstrate increased ECM protein synthesis, including type IV collagen, fibronectin, laminin, and proteoglycans, decreased synthesis of MMPs, and increased production of TIMPs.^{222–224} TGF- β_1 also stimulates glucose uptake by enhancing the expression of GLUT-1 in mesangial cells,⁵³ perhaps aggravating the metabolic abnormalities of diabetes. Several pathways can be involved in the elevated TGF- β expression in diabetes, including hyperglycemia, increased intraglomerular pressure, glycosylated proteins, PKC activation, and mechanical strain.²¹⁹ High glucose levels increase TGF- β_1 mRNA levels in mesangial cells²²⁵ and increase synthesis of F2-isoprostane, an arachidonic acid derivative, in glomerular endothelial and mesangial cells *in vitro*. Incubation of glomerular mesangial cells with F2 isoprostane also stimulates TGF- β production.²²⁶ The high glucose-stimulated increase in TGF- β production by mesangial cells is blocked by an inhibitor of isoprostane production. These findings suggest that F2-isoprostane synthesis during diabetes appears to be responsible, at least in part, for the increase in renal TGF- β . TGF- β -neutralizing antibodies reduce the *in vitro* rise in mesangial cell type IV collagen synthesis induced by high glucose levels.²²⁷ Mitogen-activated protein kinases (MAPKs) and PKC may play an important role in the glucose-induced TGF- β -mediated increase in ECM production in these cells.^{225,228} Thus, specific PKC β inhibitors may also have a role as antagonists of the TGF- β system (see below). TGF- β_1 gene overexpression has been described in rat^{220,229,230} and human diabetic glomeruli.^{99,231,232} Animal models of diabetes show increased TGF- β_1 and TGF- β_2 mRNA levels and TGF- β_2 and TGF- β type II receptor proteins.²²¹ Glomerular ECM accumulation was observed in a nondiabetic transgenic mouse overexpressing TGF- β_1 in the glomerulus,²³³ although the glomerular lesions resembled but did not fully mimic DN lesions. Further, TGF- β antibodies limited the increases in plasma renal TGF- β_1 , renal TGF- β_1 , TGF- β type II receptor, type IV collagen, and fibronectin mRNA expression, prevented the increase in serum creatinine, and reduced the diabetes-associated renal hypertrophy and MM expansion in diabetic mice.^{234,235} ACE inhibitor (enalapril) treatment decreases TGF- β type I, II, and III receptors in the glomerulus, with no changes in TGF- β isoforms, partially prevents renal hypertrophy, and completely prevents AER increase in diabetic rats.²³⁶ Thus ACE inhibitors may regulate the renal TGF- β system through decreases in TGF- β receptors.²³⁶ Interestingly, serum and urinary TGF- β_1 levels were no different between diabetic patients with or without renal impairment, and were similar to levels observed in patients with nondiabetic renal disease.²³⁷

GH and IGF

Diabetes leads to decreased hepatic production of IGF-1 and the consequent decrease in the serum IGF-1 results in excess GH secretion,²³⁸ which in turn can then stimulate local IGF-1 pathways in other tissues, such as the kidney. IGF-1 *in vitro* induces increased mesangial cell proliferation.²³⁹ Mesangial cells from nonobese diabetic (NOD) mice secrete increased amounts of IGF-1,²⁴⁰ and the consequent reduction in MMP-2 activity²⁴¹ could lead to glomerular ECM accumulation. Increased kidney levels of IGF-1 precedes renal growth in diabetic rodents. This IGF-1 renal accumulation is influenced by glycemia,²⁴² in that strict insulin therapy

blocks IGF-1 increase and renal hypertrophy in diabetic rats.²⁴³ Renal accumulation of IGF-1 is more likely to be caused by changes in renal IGF-1 receptors and IGF-1 binding proteins than by an increase in local kidney IGF-1 production.^{244,245} Long-acting somatostatin analogues²⁴⁶ and GH-receptor antagonists^{247,248} prevent the rise in renal IGF-1 and IGF binding protein-1 mRNA levels and renal hypertrophy in diabetic animals. An IGF-1-receptor antagonist prevented retinal neovascularization and VEGF increase in a rat model of nondiabetic retinopathy,²⁴⁹ indicating that VEGF may be a downstream mediator of IGF-1 actions. This hypothesis is further reinforced by the nuclear factor kappa B (NFκB) stimulation by both IGF-1 and VEGF in endothelial cells *in vitro*. NFκB is involved in the upregulation of genes encoding for cytokines, growth factors such as TGF-β, and ECM proteins such as fibronectin.²⁵⁰

VEGF

VEGF, a potent mitogen for vascular endothelial cells and a major regulator of angiogenesis, increases microvascular permeability,²⁵¹ and has been associated with proliferative retinopathy^{252,253} and neoangiogenesis^{254,255} in experimental and human diabetes. Hypoxia is a potent VEGF stimulator.²⁵⁶ In the kidney, VEGF is almost exclusively expressed in glomerular and tubular epithelial cells,^{257,258} while the VEGF type 2 receptor (VEGF-R2) is mainly present in glomerular and tubular endothelial cells, but also in interstitial cells.²⁵⁸ In high-glucose conditions, VEGF and its receptors are also expressed in glomerular endothelial and mesangial cells.²⁵⁹ Glucose stimulates VEGF expression *in vitro* in vascular smooth²⁶⁰ and mesangial^{261,262} cells, probably through the PKC pathway.^{261–263} TGF-β, PKC, and NO enhance VEGF expression in cultured mesangial cells.^{218,261,262,264} On the other hand, VEGF stimulates NO production by vascular endothelial cells *in vitro* and *in vivo*, but not by renal mesangial cells *in vitro*.²⁶⁵ Angiotensin II also stimulates VEGF in human mesangial cells.²⁶⁶ Mechanical stretching of human mesangial cells *in vitro* induces VEGF production,²⁶⁶ possibly linking glomerular hemodynamic abnormalities in diabetes to this system. Stretch and angiotensin II have additive effects on increasing VEGF expression. Interestingly, losartan, an angiotensin II receptor antagonist, and anti-TGF-β antibody, have been shown to prevent angiotensin II-induced, but not stretch-induced, VEGF production in human mesangial cells,²⁶⁶ suggesting that angiotensin II and mechanical stretch can both independently induce VEGF production. Increased proliferation of mesangial cells exposed to VEGF *in vitro* is inhibited by anti-VEGF antibody.²⁵⁹ VEGF is increased in glomeruli in diabetic animals,²⁵⁸ and diabetic rats treated with anti-VEGF neutralizing antibody do not hyperfilter and have less AER increase.²⁶⁷ Plasma and urinary levels of VEGF are increased in microalbuminuric and proteinuric patients with T1DM and T2DM,^{255,261,268} but no relationship between VEGF levels and GFR decline was found in proteinuric type 1 diabetic patients followed for 3 years.²⁵⁵ One study showed that, despite being independently correlated to microalbuminuria and retinopathy, serum VEGF levels were related to glycemic control, and improvement in glycemia resulted in a significant reduction of VEGF levels.²⁶⁸ No differences in glomerular VEGF mRNA levels were found in microalbuminuric and proteinuric type 2 diabetic patients between patients with typical or atypical diabetic glomerulopathy.²⁶⁹ Another study found stronger immunostaining of VEGF glomerular epithelial cells in type 2 diabetic patients with mild versus more advanced DN or controls.²⁶¹ VEGF staining was markedly decreased or absent in globally scler-

rotic glomeruli. However, tubular VEGF staining was more intense in advanced than in mild DN. This could be explained by podocyte loss with a consequent decrease in glomerular VEGF expression.²⁷⁰ Indeed, as is true for neoangiogenesis in diabetic retinopathy,²⁵³ VEGF could also be related to increased vascularization around the glomerular pole in DN. Blood vessel growth has been observed in experimental²⁷¹ and human²⁷² DN. However, the role of VEGF in the pathogenesis of DN is still far from clear, and it is uncertain whether VEGF expression is the cause of pathological changes, or represents a reparative response to preexisting tissue and functional alterations.

EGF

EGF is synthesized in the kidney, and mesangial, tubular, and interstitial cells all have receptors for this peptide.²⁷³ EGF stimulates *in vitro* tubular cell proliferation²⁷⁴ and thus may play a role in early diabetic renal hypertrophy.²⁷⁵ EGF strongly influences the synthesis and turnover of ECM proteins, including collagens, fibronectin, laminin, and glycosaminoglycans.²⁷⁶ In several cell types, EGF downregulates TGF-β receptor expression,^{277,278} suggesting that some EGF activities are indirect. Other growth factors including platelet-derived, fibroblast, and nerve growth factors can modulate EGF receptor activity.²⁷⁹ The human EGF receptor is phosphorylated by PKC, reducing the affinity of this receptor for EGF. Interestingly, binding of EGF to its receptor leads to formation of inositol-1,4,5-triphosphate and 1,2 diacylglycerol,²⁸⁰ stimulating PKC and thus possibly modulating the activity of this system.

PKC

The PKC enzyme regulating Na⁺/K⁺-ATPase²⁸¹ has a role in regulating cell proliferation, vascular contractility and permeability, and basement membrane synthesis. PKC can be activated by diacylglycerol,²⁸² and thus by high glucose (Fig. 42-11). PKC can increase iNOS expression and regulate NO production in mesangial cells.²⁸³ High glucose-induced PKC activation in glomerular cells *in vitro* is followed by increased TGF-β²⁸⁴ and MAPK²⁸⁵ activity. For example, the antioxidant vitamin E inhibits the glucose-induced increase in PKC, TGF-β, and ECM production in mesangial cells *in vitro*, without affecting the exogenous TGF-β-induced increase in ECM production.²⁸⁴ Increased type IV collagen expression in mesangial cells in high glucose is prevented by nonspecific PKC inhibitors,²⁸⁶ and treatment of PKC agonists can increase type IV collagen expression.²⁸⁷ Treatment with a PKCβ inhibitor blocks increases in glomerular TGF-β1 mRNA, MM, GFR, and AER in diabetic rodents.^{229,288} In another study, PKCβ inhibition prevented glomerular hypertrophy and albuminuria without affecting the TGF-β axis in diabetic rats,²⁸⁹ indicating that PKC renal effects in diabetes may at least in part be independent of the TGF-β axis.

Cytokines

As discussed above (see section on hemodynamics), there are *in vitro* and animal model data linking the pathogenesis of DN to the renin-angiotensin system.

Plasma Prorenin Levels and Diabetic Complications

Renin and its inactive precursor, prorenin, are secreted into the circulation from the kidney.²⁹⁰ Renin is derived almost entirely

from the kidney,²⁹⁰ whereas prorenin, while primarily of renal origin, is also produced in other sites.^{290,291} In longstanding diabetes with microvascular complications, plasma prorenin levels tend to be markedly elevated, but renin levels tend to be normal or reduced.^{292–294} The pathogenesis of markedly increased plasma prorenin levels in diabetic patients with complications is not completely understood but is likely of renal origin.²⁹⁵ Followed serially, only 1 of 20 young patients with T1DM with consistently normal prorenin levels developed proteinuria or retinopathy, whereas one or both developed in 8 of 14 patients with increased prorenin levels.²⁹³ Daneman and associates²⁹⁴ studied 50 adolescents with T1DM for an average of 7 years, 25 of whom had microalbuminuria. Prorenin was highest in the microalbuminuric patients versus the nonmicroalbuminuric patients, and all type 1 diabetic patients combined had higher values than controls. Most interestingly, the nondiabetic siblings of the microalbuminuric patients in this study had higher prorenin values than siblings of the nonmicroalbuminuric type 1 diabetic patients.²⁹⁴ In another report, type 1 diabetic patients developing microalbuminuria or proteinuria (progressors) had increased total renin content (which is predominantly prorenin) as early as 10 years before onset of microalbuminuria.²⁹⁶ Increase in plasma prorenin also preceded the development of microalbuminuria in patients with type 1²⁹⁷ or type 2²⁹⁸ diabetes. However, this was not confirmed in another study in patients with T2DM.²⁹⁹ Taken together, these studies suggest that elevated plasma prorenin may be an important predictor of progressive DN.

Angiotensin II

Angiotensin II elevates blood pressure through its direct vasoconstrictor, sympathomimetic, and sodium-retaining (through aldosterone release) activities. Nonhemodynamic effects of angiotensin II on renal cells may contribute to the progression of DN. Glucose may increase mesangial angiotensin II production,³⁰⁰ and angiotensin II stimulates cellular glucose uptake and transcription of GLUT-1,³⁰¹ leading to a high intracellular glucose concentration and its consequences. Angiotensin II also activates PKC in mesangial and tubular cells,³⁰² and PKC can thus activate TGF- β , promoting mesangial³⁰³ and proximal tubular³⁰⁴ cell proliferation. Angiotensin II upregulates TGF- β -receptor expression in mesangial cells *in vitro*, which could increase the sensitivity to exogenous TGF- β , enhancing TGF- β fibrogenic actions.³⁰⁵ Thus angiotensin II can stimulate *in vitro* ECM synthesis through TGF- β activity in mesangial and tubular cells,^{304,306} and can inhibit mesangial cell collagenase activity,³⁰⁷ reducing ECM turnover. These effects are blocked by losartan,³⁰⁷ an angiotensin II antagonist, and by saralasin,³⁰⁶ an angiotensin II competitive inhibitor. Angiotensin II-receptor antagonists abolish proliferative growth of murine mesangial cells.³⁰⁸ Angiotensin II can also stimulate VEGF and endothelin release (see above). Angiotensin II also activates NAD/NADP oxidase and induces superoxide production and hypertrophy by mesangial cells.³⁰⁹ Many of the angiotensin II actions are indirect, and dependent on TGF- β or VEGF release. Interestingly, diabetic rats deficient in angiotensin type 1 receptors do not show increased renal TGF- β mRNA levels, supporting the hypothesis that the increase in TGF- β in diabetes is mediated by angiotensin II.³¹⁰ The relative importance of systemically-derived versus locally-generated angiotensin II in the pathogenesis of tissue injury remains controversial.³¹¹ (see section on hemodynamics).

Bradykinin

Bradykinin, the major effector molecule of the kallikrein-kinin system, could play a role in modulating renal hemodynamics and function. Since this enzyme inhibits angiotensin II formation and also prevents degradation of vasodilatory kinins,³¹² increased bradykinin levels could have a protective effect on the progression of renal failure. Bradykinin can also increase NO levels.³¹³ Alterations in the kallikrein-kinin system have been found in experimental³¹⁴ and clinical⁶⁴ diabetes (see section on hemodynamics). Diabetic rats developing proteinuria and reduced GFR show increased serum and urinary levels of bradykinin compared to control animals.³¹⁵ A reduction in renal kallikrein has been found in type 2 diabetic patients, suggesting that an impaired renal kallikrein-kinin system contributes to the development of DN.³¹⁶ Under physiologic conditions, most of bradykinin's effects involve bradykinin-B2 receptors.³¹⁶ A bradykinin-B2-receptor antagonist had no effect on AER and glomerular ultrastructure [GBM width and Vv(Mes/glom)] when used alone or associated with an ACE inhibitor (ramipril) or an angiotensin II type 1-receptor blocker (valsartan) in diabetic rats.³¹⁷ This bradykinin-B2 receptor antagonist had previously been shown to reduce hyperfiltration⁶³ and AER³¹⁸ in diabetic rodents. It has been suggested that changes in the kallikrein-kinin system induced by ACE inhibitors may contribute to the renoprotective effect of these drugs. ACE inhibition reduces angiotensin II formation and induces bradykinin accumulation.³¹² However, a randomized, double-blind, crossover clinical trial in 16 patients with T1DM did not find differences in AER, GFR, and 24-hour blood pressure between an ACE inhibitor (enalapril) and an angiotensin II type 1-receptor blocker (losartan) used for 2 months.³¹⁹ Both drugs reduced AER and blood pressure when compared to placebo. There was no effect on GFR. These studies suggest that the renoprotective effects of ACE inhibitors are independent of bradykinin, as angiotensin II type 1-receptor blockers do not increase bradykinin levels.

Endothelins

Endothelins, potent vasoconstrictors and positive inotropic and chronotropic myocardial agents, increase the plasma levels of a number of vasoactive hormones, such as atrial natriuretic peptide, aldosterone, and catecholamines. They are produced and secreted by endothelial, epithelial, and mesangial cells.³²⁰ TGF- β , angiotensin, hypoxia, and hemodynamic shear forces increase endothelin synthesis by vascular endothelial cells.³²¹ On the other hand, endothelins can induce TGF- β synthesis and stimulate mesangial cells, smooth muscle cells, and fibroblast proliferation.^{320,321} High glucose levels induce endothelin-1 expression in rat mesangial cells,³²² and endothelin stimulation activates MAPKs [extracellular signal-regulated kinases (ERK1 and ERK2)] in a PKC-dependent mechanism.³²³ Thus PKC is necessary, but not sufficient, for mitogenic signaling by endothelin.³²⁴ Reactive oxygen species can also enhance endothelin-1 production by diabetic rat glomeruli, and reactive oxygen species scavengers suppress endothelin-1 production both *in vivo* and *in vitro*.³²⁵ Endothelins can also reduce renal blood flow and GFR.³²⁶ Endothelin-A receptor antagonist,³²⁷ insulin,³²⁸ and enalapril³²⁹ treatment ameliorated the glomerular increase of endothelin-1 mRNA in diabetic rats. Diabetic rats have higher urinary endothelin-1 excretion and AER than controls. Administration of endothelin-A/endothelin-B,³³⁰ but not of endothelin-A,³²⁷ receptor antagonist reduced AER in diabetic rats. Patients with type 1 and type 2 diabetes have higher

urinary endothelin-1 excretion than nondiabetic controls, and urinary endothelin-1 is correlated with AER and serum albumin in the diabetic patients.^{331,332} However, lower urinary excretion and higher plasma endothelin-1 levels were found in type 2 diabetic patients when compared to controls.^{333,334}

To definitively implicate the pathways discussed above (PKC, TGF- β , IGF, VEGF, and others), it is important to demonstrate that they are involved in the genesis of typical DN lesions as defined by well-established electron microscopy morphometric techniques. The lesions studied should include mesangial expansion and GBM thickening. The studies should attempt to demonstrate that these lesions can be caused by activation of these pathways in nondiabetic animals, or prevented by treatment with specific inhibitors of these pathways in animals or humans with diabetes.

Oxidative Stress

Intracellular reactive oxygen species are produced by the mitochondrial electron transport chain in response to hyperglycemia. Indeed, reactive oxygen species may arise from multiple pathways,³³⁵ including (1) glucose autooxidation; (2) hydrogen peroxide (H_2O_2), generated from the oxidation of enediols formed from Amadori products; and (3) superoxide ($O_2^{\cdot-}$), formed by the mitochondrial oxidation of NADH to NAD^+ or in the formation of prostaglandins, since prostaglandin synthase utilizes NADH (and NADPH) with generation of $O_2^{\cdot-}$. Both H_2O_2 and hydroxyl radicals ($\cdot OH$) may be derived from $O_2^{\cdot-}$. Mitochondrial superoxide overproduction stimulates aldose reductase activity, thus initiating the *de novo* synthesis of diacylglycerol, activating PKC. Reactive oxygen species can also initiate intracellular formation of advanced glycation end products (AGEs) (Fig. 42-11). Inhibitors of mitochondrial electron transport and manganese superoxide dismutase, an enzyme that leads to reactive oxygen species scavenging in mitochondrial matrix, have been shown to inhibit the production of reactive oxygen species secondary to hyperglycemia. These agents also prevent high glucose-induced PKC and NF κ B activation, methylglyoxal-derived AGE formation, and sorbitol accumulation through the polyol-pathway. This strongly suggests that reactive oxygen species are not only necessary for the damage caused by hyperglycemia, but they can also be the link between the several pathophysiologic hypotheses for DN. Methylglyoxal, the most reactive dicarbonyl AGE-intermediate in crosslinking of proteins, can regenerate reactive oxygen species in the course of glycation reactions.³³⁶ *In vitro* studies demonstrated that the antioxidant vitamin E blocks the high glucose-induced increase in PKC, and TGF- β bioactivity, as well as collagen and fibronectin synthesis in mesangial cells.²⁸⁴ Taurine, another antioxidant, also inhibits the activation of PKC and the increase in TGF- β in response to high glucose levels.²⁸⁴ In contrast, vitamin E did not alter the mesangial cell increase in matrix protein synthesis induced by TGF- β .²⁸⁴ However, treatment of diabetic rats with antioxidant agents shows controversial results. Diabetic rats treated with selenium and vitamin E³³⁷ or nitecapone, another antioxidant,³³⁸ showed reduction of AER, hyperfiltration, and glomerular lesions. Intraperitoneal injection of vitamin E also prevented glomerular increase of diacylglycerol content, PKC activity, and filtration rate and fraction, and improved AER in diabetic rats.³³⁹ However, another study found less proteinuria, albuminuria, glomerular hypertrophy, glomerulosclerosis, and tubulointerstitial fibrosis, and preserved glomerular type IV collagen staining in taurine-treated animals, while vita-

min E-treated animals had extremely high mortality and renal lesions.³⁴⁰ Both taurine³⁴¹ and vitamin E^{284,342} had previously been shown to reduce collagen accumulation in rat mesangia exposed to high glucose.

Oxidative stress is increased in diabetes.³⁴³ The debate has been whether oxidative stress has a primary role in the pathogenesis of diabetic complications, occurring at early stages in diabetes or whether it is merely a consequence of tissue damage, reflecting the presence of complications.³⁴⁴ Skin fibroblasts from type 1 diabetic patients with DN do not show the expected increase in activity and mRNA expression of the antioxidant enzymes, catalase and glutathione peroxidase, when exposed to a high-glucose concentration *in vitro*,³⁴⁵ while no differences between type 1 diabetic patients with DN and diabetic patients without nephropathy, nondiabetic nephropathic patients, and normal controls were observed when skin fibroblasts were cultured in normal-glucose conditions. Catalase promotes the transformation of hydrogen peroxide to oxygen and water, and glutathione peroxidase reduces peroxide and superoxide levels. Glutathione peroxidase requires a high cellular level of reduced glutathione to be effective. Lipid peroxidation induced by exposure to high glucose was also more pronounced in cells from type 1 diabetic patients with DN. These findings suggest that increased oxidative stress in type 1 diabetic patients with DN is associated with a decreased response of antioxidant enzymes to high glucose. Recent studies have demonstrated increased oxidative stress in families of type 1 diabetic patients,³⁴⁶ suggesting that an abnormal redox state could even precede diabetes onset. Interestingly, erythrocyte glutathione content is correlated to Na^+/H^+ exchanger (NHE) activity,³⁴⁷ linking oxidative stress to an ion transport system associated with DN risk.

There is an association between oxidative stress, altered NO production and action, and endothelial dysfunction.³⁴⁸ Endothelium-derived NO is a potent vasodilator that also has antithrombotic properties, including decreased platelet and leukocyte adhesion to the endothelium, and inhibition of smooth muscle cell migration.³⁵⁰ Endothelial NO synthesis can be stimulated by shear stress and pulsatile vessel stretching,³⁵¹ hypoxia,³⁵² and agonists such as acetylcholine and bradykinin.³⁵³ Exposure to high glucose concentrations increases eNOS gene expression and NO release, with a concomitant increase in superoxide production. Superoxide inactivates and reacts with NO to form peroxynitrite, a potent oxidant, leading to endothelial dysfunction.³⁵⁵ Normalization of NO-mediated vasorelaxation in high-glucose conditions by superoxide dismutase,³⁵⁶ a scavenger that transforms superoxide anion into hydrogen peroxide, further adds to this association. NO suppressed TGF- β activity and abolished increases in TGF- β mRNA and collagen synthesis in mesangial cells exposed to high glucose concentration. Endogenous NO produced by glomerular capillary endothelial cells may modulate TGF- β production by these cells and also by mesangial cells.³⁴⁹ Stimulation of *in vitro* iNOS activity reduces collagen and fibronectin accumulation in rat mesangial cells.³⁵⁷ NO may also modulate MMP-2 activity in these cells.³⁵⁸ High glucose *in vitro* enhances EGF- and IGF-1-, but not TGF- β - or VEGF-induced NO production by rat mesangial cells.^{265,359} This suggests that growth factors may modulate the inhibitory effects of high glucose on NO production.³⁵⁹ Decreased basal and stimulated NO release, reduced bioavailability of NO and decreased vascular smooth cell responsiveness have been shown in diabetes. Hyperglycemia may cause these abnormalities by several mechanisms, including increasing AGE production

polyol pathway, and PKC activities, as well as increasing oxidative stress, as described above. AGEs can quench NO both *in vitro* and *in vivo*,³⁶⁰ decreasing its bioavailability and impairing NO's antiproliferative effects on mesangial cells.³⁶¹ Interestingly, aminoguanidine, an AGE crosslink inhibitor, also inhibits NO⁷⁰ and restores endothelium-dependent relaxation in diabetic rats.³⁶⁰ Increased aldose reductase activity in chronic hyperglycemia causes reduced NADPH, an essential cofactor for NOS, and could thus lead to reduced NO production.³⁴⁸ Increased PKC could also lead to impaired endothelium-dependent relaxation.³⁶²

Glycosylation Products

Although the key points are summarized here, the reader is referred to the excellent review by Chen and colleagues³⁶³ and Chap. 13 for greater details on this subject. One of the major metabolic effects of diabetes are the nonenzymatic reactions between reducing sugars, such as glucose, and free amino groups, lipids, or nucleic acids.³⁶⁴ This interaction, known as the Maillard reaction,³⁶⁴ is accelerated by hyperglycemia. Many proteins, such as hemoglobin,³⁶⁵ albumin,³⁶⁴ low density lipoproteins,³⁶⁶ erythrocyte membrane proteins,³⁶⁷ and crystalline lens,³⁶⁸ undergo nonenzymatic glycosylation in diabetes, leading to altered physicochemical properties of these molecules. This early glycation process proceeds through the labile Schiff base adduct formation and intramolecular Amadori rearrangement, to become a stable glucose-modified protein. Amadori products comprise the majority of plasmatic glucose-modified proteins, and receptors for some of those modified proteins have been defined.³⁶⁹ Further modifications of Maillard reaction products lead to inter- and intramolecular crosslinks and formation of AGEs. These reactions are complex and the reader is referred to several excellent reviews for greater detail.^{370,371} It has been suggested that the accumulation of glycation products may be a major contributor to the development of diabetic complications.^{372–374} Increased AGEs can stimulate the synthesis of various growth factors, including IGF-1 and TGF- β . Binding of AGE proteins to AGE receptors on cell surfaces induces an intracellular oxidative response *in vitro*, characterized by increased NF κ B.³⁷⁵ A hallmark of the glomerular changes of diabetes is mesangial expansion, mainly due to increases in ECM. Mesangial cells exposed to high glucose concentration when the matrix is being made, or when the degradation is taking place, have a reduced rate of mesangium degradation.³⁷⁶ Thus, glycosylated ECM has reduced turnover rates, favoring ECM accumulation.³⁷⁷ Human and rat mesangial cells exposed to glycated bovine serum albumin showed increased IGF-1 and TGF- β proteins, IGF-1, IGF-2, and TGF- β ₁ mRNAs, and ECM (laminin, type IV collagen, and fibronectin) proteins and mRNAs. These effects were prevented by aminoguanidine or by an AGE-receptor 1 antagonist.³⁷⁸ Both high glucose and glycated bovine serum albumin can increase AGE-receptor expression in rat mesangial cells.³⁷⁹ Diabetes induction also increased glomerular AGE-receptor mRNA expression and increased immunohistochemical staining in diabetic rats.³⁷⁹ Further, intraperitoneal AGE-modified mouse albumin increases glomerular mRNA for TGF- β ₁ and ECM components³⁸⁰ and causes glomerular hypertrophy. These effects are reduced by aminoguanidine.³⁸⁰ Soulis-Liparota and associates³⁷⁴ found that aminoguanidine diminished the increased collagen-related fluorescence in diabetic rat aorta, glomeruli, and renal tubules, as well as albuminuria. In this study, GBM width increased in both treated and untreated diabetic rats, while Vv(Mes/glom) increase was prevented by aminoguanidine.

However, another study found that aminoguanidine ameliorated the GBM thickening but not the Vv(Mes/glom) increase in diabetic rats.³⁸¹ In similar studies [M.W. Steffes, M. Mauer, unpublished data], aminoguanidine failed to have any effect on GBM or mesangial expansion in severe longstanding diabetes in rats. More recently, oral treatment with aminoguanidine was also shown to normalize renal mRNA expression of IGF-1 and IGF-binding proteins in diabetic rats,³⁸² reinforcing a favorable effect of aminoguanidine in DN. Novel inhibitors of advanced glycation have been shown to exhibit renoprotective effects similar to aminoguanidine.^{383,384} OPB-9195, a new AGE inhibitor, reduced renal TGF- β ₁, VEGF, and type IV collagen mRNA expression, glomerular TGF- β ₁, VEGF, type IV collagen, and AGE immunoreactivity, albuminuria, and progressive glomerulosclerosis without changing glycemia, in an animal model of T2DM.^{385,386} Pimagedine, a second-generation AGE inhibitor, reduced urinary protein excretion in proteinuric type 1 diabetic patients, and also decreased the chances of doubling serum creatinine in patients with initial creatinine lower than 1.5 mg/dL.³⁸⁷ Serum AGE levels were independent predictors of progression of early structural glomerular lesions [Vv(MM/glom)] in microalbuminuric type 1 diabetic patients.³⁸⁸

Amadori-Glycated Albumin and Diabetic Nephropathy

Renal cells grown in high glucose have upregulation of the TGF- β ^{227,389,390} and PKC^{287,391} systems, and exhibit ECM overproduction.^{286,392} Amadori-glycated proteins, which are earlier products of the glycation process than AGEs, have similar cellular effects even without high-glucose media. For example, glomerular epithelial cells exposed to glycated fetal bovine serum show increased laminin and GBM antigens, unchanged type I collagen and fibronectin, and decreased collagenase activity.³⁹³ Glycated albumin and high-glucose media together cause an even greater *in vitro* increase in TGF- β ₁ and type II TGF- β -receptor mRNAs than either manipulation alone.³⁹⁴ Also, mouse mesangial cells incubated in normal glucose media containing glycated serum proteins have increased α ₁(IV) collagen and fibronectin mRNA, and these effects are intensified by high-glucose media.^{394,395} Moreover, antibody to glycated albumin prevented the increase in fibronectin and type IV collagen expression, and reduced albuminuria in rodent endothelial and mesangial glomerular cells exposed to glycated albumin.^{363,395,396} Antiglycated albumin antibody administration lowers plasma glycated albumin concentration, reduces AER, and improves glomerular mesangial pathology in *db/db* diabetic mice.^{397,398} Treatment with an inhibitor of glycated albumin formation (EXO-226) reduced AER, prevented GFR decline, and reduced MM accumulation and α ₁(IV) collagen cortical mRNA expression in *db/db* mice.³⁹⁹ Plasma concentrations of glycated albumin were normalized by treatment, despite persistent hyperglycemia.³⁹⁹ Also, when overall PKC or specifically PKC β activity are blocked, the glycated albumin-induced increase in type IV collagen production is prevented,^{229,288} consistent with the notion that PKC, particularly the β isoform, plays a role in glycated albumin-induced ECM accumulation. Type 1 diabetic patients showed higher plasma levels of glycated albumin than nondiabetic controls, and type 1 diabetic patients with DN showed higher plasma levels of Amadori albumin than normoalbuminuric patients.⁴⁰⁰ However, studies examining the role of Amadori-glycated proteins in the progression of diabetic renal disease have reached conflicting conclusions.^{401–403} Further studies of glycation's role in patho-

genesis and treatment strategies for DN are warranted. However, the fact that glycation is a nonenzymatic process dependent on the duration and magnitude of glycemia, currently leaves unexplained why only about one-half of patients with very poor glycemic control develop clinical DN.¹⁰³

Increased Activity of Aldose Reductase

Aldose reductase, the enzyme that catalyzes the reduction of glucose to sorbitol in the polyol pathway (Fig. 42-11), has been associated with DN and other microvascular complications. Aldose reductase, not present in all mammalian cells, is present in all the target tissues of diabetic complications. These tissues include kidney, lens, retinal capillary wall pericytes, vascular endothelium, and peripheral nerve (Schwann cells). Increased activity of aldose reductase leads to accumulation of sorbitol, which is further converted to fructose by the sorbitol dehydrogenase enzyme, using NAD^+ as substrate. The ratio of $\text{NAD}^+:\text{NADH}$ decreases and the conversion of glyceraldehyde 3-phosphate to 1,3-bisphosphoglycerate is blocked, leaving more substrate (glyceraldehyde 3-phosphate) for the synthesis of α -glycerol phosphate, a diacylglycerol precursor. Diacylglycerol is a PKC activator that, as discussed, could regulate ECM synthesis and removal. Also, increased activity of aldose reductase consumes NADPH, leading to decreased or depleted glutathione. Glutathione is an antioxidant coenzyme used by glutathione peroxidase to reduce peroxides or superoxide, as described above, yielding oxidized glutathione. Glutathione can also act as a detoxicant for carbonyl compounds.³⁴⁴ Hypertonicity stimulates aldose reductase gene expression, and kinases (p38-MAPK and ERKs) appear to be involved in the regulation of this response.⁴⁰⁴ Both glucose and H_2O_2 activate p38-MAPK *in vitro*, suggesting that increased glucose may contribute to increased aldose reductase expression, independently of hyperosmotic conditions. PKC also has a role in controlling aldose reductase gene transcription.⁴⁰⁵ Moreover, reactive oxygen species decrease NO content, which activates aldose reductase. Increased aldose reductase activity may also contribute to impaired renal autoregulation.

FIGURE 42-11. The effects of increased activity of the polyol pathway. The metabolism of glucose to sorbitol and fructose in the polyol pathway decreases the $\text{NADPH}:\text{NADP}^+$ and $\text{NAD}^+:\text{NADH}$ ratios. Consumption of the NAD^+ in the conversion of sorbitol to fructose (*) may limit 1,3-bisphosphoglycerate formation (**), resulting in increased diacylglycerol and protein kinase C (PKC) activation. The consumption of NADPH in the conversion of glucose to sorbitol (†) may result in decreased production of glutathione, an antioxidant coenzyme used by glutathione peroxidase to reduce peroxide and superoxide levels. PPP, pentose phosphate pathway.

tion.⁴⁰⁶ An aldose reductase inhibitor prevents type IV collagen and fibronectin accumulation in human renal proximal tubular cells exposed to high glucose levels.⁴⁰⁷ Treatment of diabetic animals with aldose reductase inhibitors has generated divergent results.^{408–41} One study showed prevention of renal and glomerular hypertrophy but not of GBM thickening,⁴¹¹ by aldose reductase inhibition while another reported prevention of mesangial expansion.⁴¹² Tolrestat, an aldose reductase inhibitor, prevented increased GFR, AER, and glomerular hypertrophy, and attenuated the accumulation of basement membrane-like material in diabetic rats, with no effect on mesangium expansion.⁴¹³ Peripheral blood mononuclear cell aldose reductase mRNA levels are increased in patients with type 1 diabetes and DN, but not in diabetic patients without nephropathy.⁴¹⁴ Aldose reductase inhibitors have a partial^{415,416} or no^{417,418} effect in ameliorating renal microvascular complications in human studies.

Steno Hypothesis

According to the Steno hypothesis, albuminuria reflects widespread vascular damage.⁴¹⁹ Heparan sulfate is the main glycosaminoglycan component of glomerular basement membranes.⁴²⁰ Hyperglycemia can lead to partial depletion of heparan sulfate from both decreased synthesis and reduced sulfation levels.⁴²¹ Decreased renal heparan sulfate can diminish the glomerular capillary wall electrostatic charge barrier.⁴²² Abnormal glomerular charge permselectivity has been observed in diabetic rats⁴²³ and humans,⁴²⁴ suggesting that loss of glomerular capillary wall proteoglycans may be responsible for the initial increase in the excretion of negatively-charged albumin.^{420,425} Changes in heparan sulfate have also been associated with other diabetic complications.^{426,427} Administration of a modified heparin glycosaminoglycan preparation to cultured mesangial cells exposed to high glucose caused inhibition of TGF- β_1 overexpression, probably through inhibition of glucose-induced PKC activation.⁴²⁸ The changes in the balance of $\alpha_1(\text{IV})$ collagen, MMP-2, and TIMP-2 in human and murine cells exposed to high glucose were partially reversed by heparin supplementation.⁴²⁹ Animal studies have shown that subcutaneous administration of low molecular weight heparin, perhaps by inducing heparan sulfate synthesis, prevented increased AER, GBM, and $\alpha_1(\text{IV})$ collagen expression and deposition in diabetic rats.^{430–432} Reduction in AER was also reported after treatment with subcutaneous low molecular weight heparin or similar drugs in microalbuminuric and proteinuric type 1^{433–436} and type 2⁴³⁷ diabetic patients, but the results are still controversial.⁴³⁸ Danaparoid, a mixture of sulfated glycosaminoglycan consisting mainly of heparan sulfate, not only decreased AER,⁴³⁵ but also reduced retinal hard exudates in proteinuric type 1 diabetic patients.⁴³⁹ These studies suggest that decreased glycosaminoglycans can have a pathogenic role in the development of diabetic complications. However, it is also clear from earlier discussions (see sections on pathology and structural-functional relationships, above) that important DN lesions can develop in patients with normal glomerular permselectivity. Thus, measurably abnormal glomerular permselectivity is not necessary for the genesis of DN lesions.

CONCLUSIONS

Several mechanisms have been proposed to explain the development of renal complications in diabetes. It appears that multiple

pathways interact and are involved in a process that is probably genetically regulated. Recent advances in molecular biology and genetics should allow us to gain new insight into the molecular mechanisms and genes involved in the development of DN. These advances will allow early identification of patients who are at risk of developing DN, and should lead to the design of specific preventive strategies that are based on this new understanding of the pathophysiologic bases of DN. Moreover, the demonstration that DN lesions are reversible could lead to treatment aimed at stimulating the healing capacities of the kidney, with the goal of restoring lost function or preventing further loss.

Diabetic Nephropathy

Ralph A. DeFronzo

INTRODUCTION

Renal disease is an all too common occurrence in individuals with diabetes mellitus. Approximately 1 million people in the United States have type 1 (previously called insulin-dependent) diabetes mellitus (T1DM), and of these, 30–40% eventually develop end-stage renal failure.¹ Unfortunately, there is little evidence that the incidence of diabetic nephropathy in type 1 diabetics has changed within the last decade.² Type 2 (previously called non-insulin-dependent) diabetes mellitus (T2DM) affects about 16 million people in the United States, but the incidence of renal disease is lower, 5–10%.^{3–5} However, the incidence of nephropathy in patients with T2DM varies considerably among ethnic groups, being 3–4 times higher in blacks and Hispanics and 7 times higher in Native Americans compared to whites^{6–8} (Fig. 43-1). Nevertheless, in absolute terms, more patients with type 2 than type 1 diabetes eventually progress to end-stage renal failure. The magnitude of the problem can be readily appreciated when it is realized that every third patient who is started on dialysis has diabetes mellitus⁹ and that the Medicare payment for patients with diabetes is ~\$51,000 per year per patient.¹⁰

DIABETIC NEPHROPATHY

Diabetic nephropathy was first described by Kimmelstiel and Wilson¹¹ in 1936. Since this original description, numerous studies have documented the renal histologic changes and the clinical course of renal dysfunction, which is characterized by hypertension, edema, severe albuminuria, and a progressive decline in glomerular filtration rate (GFR).⁵ Three major histopathologic alterations have been described in the diabetic kidney: glomerulosclerosis, vascular involvement, and tubulointerstitial disease.^{12–14}

Glomerulosclerosis

Involvement of the glomeruli is the most characteristic feature of diabetic nephropathy, and proteinuria and/or a reduction in GFR are the most common laboratory abnormalities that signify the presence of glomerular dysfunction. Three distinctive glomerular lesions have been described: diffuse intercapillary glomerulosclerosis, nodular glomerulosclerosis, and glomerular basement membrane (GBM) thickening (Fig. 43-2).

Diffuse and Nodular Lesions

The most common histologic abnormality, diffuse intercapillary glomerulosclerosis, is characterized by increased, periodic

acid-Schiff (PAS)-positive, eosinophilic material within the mesangial region (see Fig. 43-2A). The increase in mesangial matrix material is diffuse, involving the entire glomerulus, and generalized, affecting all glomeruli throughout the kidney. With time, there is a progressive expansion of the mesangial material, which encroaches on adjacent capillary lumina. As this process progresses, entire glomeruli become hyalinized. There is no increase in mesangial cell number, but mesangial cell volume is increased.¹⁵ In 40–50% of patients, the increase in mesangial matrix forms large acellular (Kimmelsteil-Wilson) nodules at the center of peripheral glomerular lobules (see Fig. 43-2B). This nodular lesion invariably is associated with the diffuse lesion and is pathognomonic of diabetes mellitus, although it correlates poorly with the severity of clinical renal disease. The best predictor of clinical renal disease is the diffuse increase in mesangial matrix material (see Chap. 42).^{13,15}

Immunofluorescent staining of the glomerulus reveals diffuse linear deposition of immunoglobulin G (IgG) along the GBM. Although this linear pattern of immunoglobulin deposition is reminiscent of anti-GBM nephritis, eluted IgG has no affinity for the GBM and most likely represents nonspecific trapping of filtered proteins.

Basement Membrane Thickening

GBM thickening represents an early and characteristic abnormality in patients with diabetic glomerulosclerosis (see Fig. 43-2A). Basement membrane thickening is not limited to the glomerulus and can be observed in capillaries throughout the body, including muscle, skin, and retina.

The GBM is a collagen-like protein that is synthesized by the visceral epithelium of the glomerulus.¹² The integrity of the GBM is maintained by the continuous addition of new material from the epithelial aspect and by the simultaneous removal from the endothelial side by mesangial cells. The half-life of the GBM is about 100 days. Both increased epithelial synthesis and impaired removal by mesangial cells contribute to the basement membrane thickening.

There are significant differences in the collagen and protein content of the normal GBM compared with basement membranes from nonrenal tissues.¹⁶ These differences in chemical composition account for the high glomerular filtration coefficient, which permits a water flux that is 50–100 times greater than in other capillaries, yet totally restricts the passage of serum proteins. The ability to restrict proteins selectively is also related to the strong negative charge provided by heparin sulfate and sialic acid residues within the GBM.

In patients with diabetic nephropathy, a number of biochemical alterations in the composition of the GBM have been described.^{16,17}

FIGURE 43-1. Incidence of nephropathy according to the duration of type 1 diabetes mellitus. (Adapted from Krolewski et al.¹)

In experimental models of diabetes, an increased activity of glucosyltransferase, the enzyme involved in the assembly of hydroxylysine-linked carbohydrate units, has been demonstrated, and restoration of normoglycemia with insulin normalized the activity of this enzyme. These results suggest that the accelerated synthesis of hydroxylysine-glucose-galactose subunits contributes to the GBM thickening. However, other investigators have reported GBM thickening without alteration in amino acid or glucosyl-galactose content in diabetic GBM. This polyantigenic expansion, involving all of the intrinsic components of the GBM and mesangium,¹⁸ suggests an overall increase in the synthetic rate of normal basement membrane, a decrease in its rate of degradation, or some combination thereof. In diabetic patients with advanced nephropathy, the sialic acid and heparin sulfate proteoglycan content of the GBM is uniformly diminished, and this decrease in anionic charge may contribute to the increased clearance of negatively charged macromolecules, such as albumin.¹⁹ *In vitro* studies employing isolated glomeruli have shown that glucose stimulates its own incorporation into capillary basement membrane in a dose-dependent fashion. Excessive glycosylation of the GBM may render collagen more resistant to degradation and contribute to the GBM thickening.

Vascular Involvement

The kidneys of patients with established diabetic nephropathy commonly manifest accelerated renal arteriosclerosis and arteriolosclerosis (see Fig. 43-2B). In the larger arteries, atheromatous changes often are advanced and may contribute to renal failure by causing ischemic parenchymal atrophy. In the smaller renal arterioles, hyaline thickening involves the afferent and efferent vessels, and is believed to play an important role in the development of hypertension. Although arteriosclerosis and arteriolosclerosis may be extensive, neither process correlates with the severity of glomerular change.

Tubulointerstitial Disease

Tubulointerstitial histologic changes (see Fig. 43-2C) are common in the diabetic kidney, and in advanced cases, there is marked tubular atrophy, thickening of the tubular basement membrane, and interstitial fibrosis.^{14,20,21} Similar changes also may be observed

FIGURE 43-2. a. Diffuse diabetic glomerulosclerosis with marked mesangial matrix hyperplasia (**thick arrows**) and thickened glomerular basement membranes (**thin arrows**). No hypercellularity is evident. b. Nodules (**thick arrows**) usually are observed in the peripheral capillary loops and rarely are seen without the diffuse lesion. Note the prominent arteriolosclerosis in the efferent and afferent arterioles. c. Interstitial fibrosis, tubular atrophy (**thick arrows**), and thickening of the tubular basement membranes. (Reproduced with permission from DeFronzo RA: *Diabetes and the kidney: an update*. In: Olefsky JM, Sherwin RS, eds. *Diabetes Mellitus: Management and Complications*. Churchill Livingstone; 1985:161.)

with renal ischemia, but in diabetes, the tubular changes correlate poorly with the degree of vascular involvement and frequently occur in their absence. Immunofluorescent studies have demonstrated deposition of IgG along the tubular basement membrane of the involved tubules. The interstitial area surrounding the tubules is fibrotic and may contain a cellular infiltrate of lymphocytes and

plasma cells. These changes progress with increasing duration of the diabetes.^{13,14}

Asymptomatic bacteriuria and pyelonephritis are twice as common in patients with diabetes, particularly women, than in patients without diabetes.²² This increased incidence of urinary tract infection results from a variety of factors, including impaired renal blood flow, bladder dysfunction, interstitial scarring, impaired polymorphonuclear leukocyte function, defective leukocyte chemotaxis, and glucosuria, which enhance bacterial growth. Although patients with diabetes are more likely to develop urinary tract infections, a clear-cut relationship between the frequency or severity of interstitial changes and urinary tract infection has not been demonstrated, and patients whose bacteriuria was not eradicated fared no worse than those in whom the bacteriuria was cured.²³ The tubulointerstitial changes most likely represent a direct manifestation of the altered metabolic milieu that results from insulin lack and/or insulin resistance. The only tubular lesion that is characteristic of the diabetic state is the *Armanni-Ebstein lesion*, a vacuolization of the proximal tubular cells of the pars recta. These vacuoles contain glycogen and are most often observed in poorly controlled patients.

Diabetes mellitus accounts for over half of all reported cases of a special type of interstitial lesion, *papillary necrosis*.²⁴ Papillary necrosis results from ischemic damage to the inner medulla with eventual infarction and sloughing of part or all of the papilla. Patients with papillary necrosis may present either with an acute fulminant illness, with fever, shock, flank pain, gross hematuria, pyuria, oliguria, and renal failure, or with a more subacute form of the disease that is characterized by microscopic hematuria, pyuria, and indolent renal failure. Urinary tract obstruction and pyelonephritis cause renal papillary necrosis. Because phenacetin has been associated with papillary necrosis, chronic use of this analgesic should be avoided in the diabetic population.

PATHOGENESIS OF DIABETIC GLOMERULOSCLEROSIS

Both genetic and acquired (metabolic/hemodynamic) factors have been invoked to explain the development of diabetic renal disease (Table 43-1). The acquired theory postulates that the renal changes are caused by a combination of metabolic and hemodynamic changes that result from a lack of insulin. The second theory argues that genetic factors are primarily responsible for the alteration of renal structure and function. As discussed below, there is strong evidence to implicate both metabolic/hemodynamic alterations and genetic factors in the pathogenesis of diabetic nephropathy.

Acquired (Metabolic/Hemodynamic) Theory

Many *in vivo* and *in vitro* studies in both humans and animals indicate that diabetic nephropathy is an acquired disorder. First, renal involvement is absent in newly diagnosed diabetic patients (Table 43-3). Histologic abnormalities, including basement membrane thickening, expansion of the mesangium, and vascular changes, do not become evident until at least 2–3 years after the onset of diabetes.^{12,13,25} Second, all of the characteristic histopathologic changes of diabetic nephropathy occur in patients with pancreatic diabetes (e.g., hemochromatosis, chronic pancreatitis, pancreatotomy),²⁶ conditions in which genetic factors are not thought to be involved. Third, diabetic nephropathy can be produced in various animal models, including the rat, mouse, dog, and monkey, regardless of the means of induction of diabetes, and treatment of hyperglycemia with insulin completely reverses or prevents diabetic renal disease.^{27–31} Fourth, transplantation of pancreatic islets into insulinopenic diabetic rats prevents the development of renal lesions.^{32,33} Fifth, when rat kidneys with established diabetic nephropathy are transplanted into nondiabetic rats, the renal

TABLE 43-1. Metabolic and Genetic Theories of Diabetic Nephropathy

Metabolic/Hemodynamic (Acquired) Theory	Genetic Theory
Renal involvement is absent when diabetes first is diagnosed. Basement membrane thickening and mesangial changes do not become manifest until 2–3 years later.	Marked variation in the incidence of nephropathy among non-insulin-dependent diabetes mellitus patients from different ethnic groups.
Typical changes of diabetic nephropathy have been observed in pancreatic diabetes (hemochromatosis, chronic pancreatitis, pancreatectomy, and cystic fibrosis).	Poor correlation exists between diabetic glomerulosclerosis and the degree of diabetic control as judged by blood glucose levels.
In the dog, monkey, rat, and mouse, lesions similar to those observed in human diabetic nephropathy have been documented after the induction of diabetes.	Excellent glucose control with the insulin pump (artificial pancreas) for 1–2 years has failed to reverse clinically overt proteinuria, and most diabetics have experienced progressive proteinuria and azotemia.
Tight regulation with insulin prevents the development of renal lesions in all diabetic animal models.	Only a minority of pancreatic diabetics develop glomerulosclerosis.
Transplantation of kidneys from diabetic into normal rats cures the renal disease.	Diabetic nephropathy has been reported early in the course of diabetes, the prediabetic state, and occasionally in patients with normal glucose tolerance.
Tight glycemic control before or during the phase of microalbuminuria can prevent or halt the progression of microalbuminuria.	Diabetic nephropathy clusters within families in individuals with both type 1 and type 2 diabetes mellitus.
Normal human kidneys, transplanted into diabetic patients, develop changes of diabetic nephropathy within 2–5 years.	Sib-pair linkage studies have shown an association between diabetic nephropathy and specific chromosomal regions, although no specific genes have yet been identified.
Transplantation of diabetic kidneys into nondiabetic patients leads to a resolution of the diabetic renal lesion.	
Pancreatic transplantation reverses established lesions of diabetic nephropathy.

FIGURE 43-3. Natural course of diabetic nephropathy. At the initial diagnosis, renal function and glomerular histology are normal. Within 2–3 years, increased mesangial matrix and basement membrane thickening are observed. Renal function remains normal until 15 years, when proteinuria develops. This is an ominous sign and usually indicates advanced diabetic glomerulosclerosis. Within 5 years after the onset of proteinuria, elevation of the serum urea nitrogen and creatinine levels are observed, and within 3–5 years after the development of azotemia, half of the patients have advanced to end-stage renal insufficiency. **GFR**, glomerular filtration rate. (Modified from DeFronzo RA: *Diabetes and the kidney: an update*. In: Olefsky JM, Sherwin RS, eds. *Diabetes Mellitus: Management and Complications*. Churchill Livingstone:1985:169.)

lesions resolve.³⁴ Conversely, transplantation of normal kidneys into diabetic rats leads to the development of diabetic nephropathy. Sixth, when kidneys from healthy persons are transplanted into diabetics, all of the typical histologic changes of diabetic nephropathy develop within 2–5 years.²⁵ The Diabetes Control and Complications Trial (DCCT), in a study carried out in 1441 patients with T1DM, has conclusively demonstrated that intensive insulin therapy can reduce the development of nephropathy.³⁵ Tight glycemic control reduced the occurrence of microalbuminuria (40–300 mg/d) and of overt albuminuria (>300 mg/d) by 39% and 54%, respectively. Intensified insulin therapy was effective both in primary and secondary prevention of nephropathy (Fig. 43-4).³⁵

The importance of the metabolic and hemodynamic environment is underscored by a case report in which kidneys were trans-

planted from a patient with T1DM with established proteinuria and biopsy-proven diabetic nephropathy into two patients without diabetes.³⁶ Seven months postrenal transplantation, renal function in both recipients was normal, proteinuria had disappeared, and renal biopsy showed resolution of the diffuse diabetic glomerulosclerosis. Similarly, others have demonstrated the regression of established diabetic nephropathy in patients after pancreatic transplantation. Lastly, pancreatic transplantation has been shown to reverse established lesions of diabetic nephropathy.³⁷

Genetic Theory

Several lines of evidence support an important role for genetic predisposition in the development of diabetic nephropathy. Although the level of glycemic control, as documented by the HbA_{1c}, correlates well with the development of proteinuria and diminished GFR,^{4,6,35} it is not uncommon to see patients whose glycemic control is quite poor, yet who do not develop diabetic nephropathy. This observation has been cited by proponents of the genetic theory as evidence for the role of genes in the development of diabetic nephropathy. Evidence can be mustered both to support and to refute the role of metabolic control in the pathogenesis of diabetic complications.

In short-term studies with a follow-up of 1–2 years, the achievement of good metabolic control has failed to reverse or ameliorate established nephropathy or to prevent the emergence of new cases of diabetic renal disease.^{38–40} This information has been offered in favor of inheritance (genes) as the primary determinant of diabetic nephropathy. However, the follow-up period in these studies was short, less than 2 years, and insulin pump therapy was not initiated until after patients had had their diabetes for many years.^{38–40} Major renal hemodynamic and structural changes occur within the initial 2–3 years after the diagnosis of diabetes and, if allowed to persist, may lead to fixed, irreversible alterations that may be responsible for the relentless progression to renal insufficiency.

FIGURE 43-4. Effect of intensive versus conventional glycemic control with insulin on the albumin excretion rate in T1DM patients. Tight glycemic control significantly reduced the risk of developing microalbuminuria (cross hatched area) and macroalbuminuria (stippled area) in normoalbuminuric patients. (Reproduced with permission from DCCT Research Group.¹⁵)

Consistent with this, the Epidemiology of Diabetes Interventions and Complications (EDIC) study (follow-up of the DCCT) failed to demonstrate any decrease in the rate of microvascular complications following 4 years of improved glycemic control in patients with T1DM who had been in poor glycemic control ($HbA_{1c} \sim 9.0\%$) over the preceding 10 years.⁴¹ On the other hand, after 5–10 years of successful pancreatic transplantation, improvement in renal structure and function has been demonstrated.³⁷ These results suggest that it takes many years of improved glycemic control to reverse the changes of established diabetic nephropathy. Blood pressure is an important determinant of renal disease in patients with diabetes, and failure to meticulously control both systolic and diastolic hypertension has been shown to offset the benefit of improved glycemic control to slow the progression of established diabetic nephropathy.⁴²

Although diabetic glomerulosclerosis has been shown to occur in patients with secondary causes of diabetes (i.e., hemochromatosis, cystic fibrosis, etc.), it occurs in only a minority of such individuals. Moreover, occasional cases of diabetic nephropathy have been shown to occur early in the course of diabetes or in the prediabetic state. Cases of typical diabetic glomerulosclerosis also have been documented in patients without glucose intolerance. Such evidence has been used to argue for a genetic etiology of renal disease in diabetic patients.^{26,43} A genetic component to the GBM thickening also has been suggested by the finding of muscle capillary basement membrane thickening in adult T1DM patients at the time of diagnosis.⁴⁴ However, these later observations have been refuted by others.⁴⁵

More direct evidence for a genetic etiology of diabetic nephropathy in patients with both type 1 and type 2 diabetes derives from the familial clustering of diabetic nephropathy (Fig. 43-5) and increased albumin excretion rates and hypertension in nondiabetic family members,^{46–50} as well as from studies of glomerular structure in sibling pairs of patients with T1DM.⁵¹ Sib-pair linkage analysis has demonstrated several chromosomal regions that are associated with diabetic nephropathy in Pima Indians,⁵² who have the highest documented incidence of diabetic renal disease in the world. A number of candidate genes have been proposed and this topic is the subject of a recent review.⁵³

In conclusion, it is likely that both metabolic and hemodynamic disturbances play an important role in the development of

diabetic nephropathy. The best synthesis of the available data indicates that metabolic derangements operate on a genetic background, which predisposes the kidney to the development of diabetic glomerulosclerosis in patients with poor glycemic control. The marked difference in renal disease among different racial groups^{6–8,54} also emphasizes the important role of genetic factors in the etiology of diabetic renal disease.

PATHOGENESIS OF DIABETIC NEPHROPATHY

Two major causative factors have been implicated in the development of diabetic nephropathy: metabolic and hemodynamic⁵⁵ (Fig. 43-6). In the absence of chronic hyperglycemia, renal disease does not occur and correction of hyperglycemia prevents the subsequent development of diabetic nephropathy.^{35,61–67} Hyperglycemia has a direct toxic effect on renal cells and leads to the formation of advanced glycosylation end-products (AGEs), activation of protein kinase C (PKC), increased growth factors, and production of cytokines, which collectively cause an increase in extracellular matrix formation.⁵⁵ Of the cytokines, transforming growth factor- β (TGF- β) has been the most extensively studied.^{55,57,68,69} It is expressed in all glomerular cells and its production is markedly accelerated in both human and animal models of diabetic nephropathy in response to hyperglycemia, angiotensin II, and AGEs. This has led to the postulate that TGF- β may represent a final common element in fibrotic diseases, including diabetic nephropathy. Vascular endothelial growth factor (VEGF) and epidermal growth factor (EGF) also have been implicated in experimental renal disease. Hyperglycemia directly glycosylates proteins in the kidney, and the presence of reduced GFR, AGEs in the circulation accumulate in the kidney where they are taken up by specific receptors, resulting in the release of growth factors and stimulation of collagen formation.^{70,71} PKC, which is activated by hyperglycemia, increases endothelial cell permeability to albumin, stimulates matrix protein synthesis by mesangial cells, and increases the production of vasodilatory prostaglandins, which may contribute to early renal hyperperfusion and hyperfiltration.^{55–57} Increased glucose flux through the aldose reductase pathway leads to the accumulation of a variety of polyols and intracellular depletion of myoinositol

FIGURE 43-5. Prevalence of end-stage renal disease (ESRD) and albuminuria in siblings of type 1 diabetic individuals (probands) with and without diabetic nephropathy. (Reproduced with permission from Seaquist et al.⁴⁶)

FIGURE 43-6. Pathogenic schema depicting the contribution of metabolic and hemodynamic factors to the development of diabetic nephropathy. A-II, angiotensin II; PKC- β II, protein kinase C; VEGF, vascular endothelial growth factor.

which can lead to the activation of PKC. In various animal models of diabetes, inhibition of the beta II isoform of protein kinase C (PKC- β II) prevents the development of hyperfiltration and albuminuria⁷² and PKC inhibitors currently are undergoing clinical testing in humans.

Systemic and local renal hemodynamic factors also play an important role in the development of diabetic nephropathy.⁵⁵⁻⁵⁷ The important contribution of systemic hypertension was discussed earlier. In diabetic animal models, there is a marked increase in single-nephron glomerular filtration rate, renal plasma flow, and intraglomerular pressure, and this constellation of renal hemodynamic changes is also observed in human diabetes. The increase in intraglomerular pressure results from enhanced sensitivity of the efferent arteriole to angiotensin II. In diabetic rats, these renal hemodynamics changes can be reversed by insulin therapy. Increased single-nephron renal plasma flow and glomerular transcapillary fluid pressure, whether due to non-diabetic renal disease or diabetes mellitus, if sustained over a prolonged period, cause cellular injury, proliferation of mesangial matrix material, and glomerulosclerosis (Fig. 43-6). The elevation in glomerular plasma flow and transcapillary hydraulic pressure leads to increased transcapillary albumin flux, which may further exacerbate the mesangial cell injury and cause the proliferation of mesangial matrix material. At the onset of nephropathy, albuminuria results from changes in either glomerular charge selectivity or altered tubular handling of filtered proteins.⁷³⁻⁷⁵ With progressive renal injury, permselectivity changes in the glomerular barrier occur and further exacerbate the proteinuria.⁷⁶ Consistent with this pathogenesis, in diabetic animal models ACE inhibitors decrease intraglomerular pressure, lower GFR and renal plasma flow, reduce proteinuria, and prevent the histologic changes of diabetic nephropathy. Improved renal function also has been observed in both type 1 and type 2 patients who are treated with ACE inhibitors. It should be noted, however, that angiotensin II has a number of nonhemodynamic actions⁷⁷ which would be expected to exacerbate diabetic nephropathy. Angiotensin II is a potent growth factor that directly augments mesangial matrix proliferation, stimulates collagen and fibronectin synthesis, causes renal hypertrophy, enhances renal TGF- β expression, and potentiates the effect of a variety of growth factors on the kidney.^{78,79} It is likely, therefore, that the renal protective effect of ACE inhibitors is multifactorial in origin.

A parallel view holds that the changes in intrarenal hemodynamics and renal hypertrophy are related to altered sodium transport in the proximal tubule and activation of the tubuloglomerular feedback reflex.⁸⁰ In diabetes the increased filtered load of glucose is reabsorbed in concert with sodium in the proximal tubule.⁸¹ The reduction in delivery of salt to the distal tubule activates the tubuloglomerular feedback reflex, leading to vasodilation and increased GFR until distal salt delivery returns to its normal set point. The increased reabsorptive work of the proximal tubule leads to the generation of metabolic growth factors, which cause renal hypertrophy with further augmentation of renal plasma flow and GFR. Most recently, this hypothesis has been challenged by Thomson and associates,⁸² who have provided evidence that the initial kidney growth that occurs in response to hyperglycemia is the primary pathogenic disturbance. The resultant renal hypertrophy causes increased proximal tubular reabsorption of sodium, which activates the tubuloglomerular feedback loop, leading to renal vasodilation and hyperfiltration. At present, it remains unresolved whether abnormalities in vascular control (renal vasodilation and early hyperfiltration) represent the primary disturbance and result secondarily in

renal hypertrophy via activation of the tubuloglomerular feedback loop, or whether the renal hypertrophy is primary and leads secondarily to stimulation of tubuloglomerular feedback and elevated renal plasma flow and GFR.⁸³

In summary, hyperglycemia sets in motion a number of hemodynamic and metabolic abnormalities that eventuate in the typical histologic and clinical picture that is seen in patients with diabetic nephropathy.

CLINICAL COURSE

Epidemiologic studies have documented that less than half of all patients with T1DM who have had their disease for 20–30 years develop clinically significant renal disease (Fig. 43-7).^{1,2,55,84} Unfortunately, at the time of diagnosis, there are no clinical or laboratory findings that predict which patients will progress to end-stage renal failure.^{55,85} Although it is often stated that the incidence of glomerulosclerosis is higher in patients with T1DM (30–40%) than in patients with T2DM (5–10%), Pima Indians have the highest incidence of T2DM and diabetic nephropathy in the world.^{86,87} Recent studies suggest that the incidence of renal disease may be more similar than previously appreciated in patients with type 1 and type 2 diabetes.^{88,89} The dramatic rise in the incidence of renal disease in patients with T2DM may result from enhanced awareness and improved treatment of hypertension and dyslipidemia, which allows patients with T2DM to live longer, thereby exposing them to a greater burden of hyperglycemia.

Early Changes in Renal Function

Early in the course of diabetes (see Fig. 43-3) the GFR is characteristically increased and correlates with increased kidney weight and size, increased glomerular volume, and increased capillary luminal area per glomerulus.^{55,86,90} During this same period, renal biopsy has demonstrated the presence of increased mesangial matrix and basement membrane thickening. Institution of intensive short-term (1–2 weeks) blood glucose control normalizes the GFR without any reduction in renal size,⁹¹ suggesting that the augmented GFR is not causally related to the renal hypertrophy. However, within 6 weeks after the start of intensive insulin therapy, a

FIGURE 43-7. The Medicare incidence of end-stage renal failure in Native Americans, African-Americans, Asian-Americans, and white Americans as a function of age. (Adapted from Teusch S, Newman J, Eggers P: *The problem of renal failure in the United States: an overview*. Am J Kidney Dis 1989;13:11.)

significant reduction in kidney size can be demonstrated in patients with T1DM.⁹² Experimental diabetes in animals is also associated with an augmented GFR, which correlates with increased glomerular volume and glomerular capillary length and diameter. All of these changes are reversible with insulin treatment or islet cell transplantation.^{29–34}

In early diabetes, no consistent change in renal plasma flow (RPF) has been observed. Although an increase in RPF has been reported by some investigators, most have found blood flow to the kidney to be normal. In all studies, the filtration fraction (GFR/RPF) was elevated.⁵⁵

Late Changes in Renal Function

Patients who are destined to develop renal insufficiency follow a predictable clinical course^{55,85,86} (see Fig. 43-3). After the onset of overt diabetes mellitus, there is a long (15–18 years) silent period, during which there is no laboratory evidence of renal dysfunction. However, if one were to perform a renal biopsy, a widespread increase in mesangial matrix material, capillary GBM thickening, interstitial fibrosis, and arteriosclerosis would be evident. Patients with clinical nephropathy had slightly more mesangial matrix material and fewer open glomerular capillaries than patients with diabetes without clinical nephropathy (see Chap. 42). The increase in mesangial matrix is inversely correlated with the area of open capillary loops. These observations suggest that in the advanced stages of diabetic nephropathy, encroachment of capillary lumina by the expanding mesangial matrix material contributes to the decline in GFR. However, nonstructural factors also must play an important role in the decay of renal function, because the severity of diabetic glomerulosclerosis in patients without clinically evident renal disease can be as marked as in patients with advanced renal insufficiency.^{93,94}

STAGING OF DIABETIC NEPHROPATHY

Microalbuminuria is the earliest clinically detectable stage of diabetic nephropathy,^{95–97} and patients with microalbuminuria are sometimes said to have *incipient diabetic nephropathy* because of their increased risk of clinical nephropathy.^{55,85,86,89} The albumin excretion rate in healthy people ranges from 2.5–25 mg/d, with a mean of approximately 10 mg/d⁹⁵ (Table 43-2). The Albustix[®] reaction does not become positive until the albumin excretion rate exceeds 300 mg/d. Thus there is a wide subclinical range (30–300 mg/d) in which urinary albumin excretion is increased, but in the past could not be detected by routine laboratory methods. However, sensitive radioimmunoassay techniques have been developed to accurately measure albumin excretion at these lower rates.⁹⁸ Patients with an albumin excretion rate of 30–300 mg/d are defined

as having microalbuminuria (Table 43-2). T1DM patients with microalbuminuria have a 20-fold increased likelihood of developing clinical proteinuria (>300 mg/d of albumin) or a diminished GFR within a period of 10 years.^{95–97} Patients with high-grade microalbuminuria (>100 mg/d) are at particularly high risk of developing renal impairment.^{55,85,86} Microalbuminuria also precedes the development of diabetic nephropathy in patients with T2DM,^{55,85,86,89,99–101} although it is not as strong a predictor as in patients with T1DM. Microalbuminuria is a very strong predictor of macrovascular complications (heart attacks, stroke) in all patients with diabetes (Fig. 43-8).^{85,99,102–104} A recent review¹⁰⁵ of the relationship between microalbuminuria and the eventual development of clinical proteinuria and reduced GFR underscores the need for the development of other early predictors (i.e., newer imaging techniques, discovery of genes that predict increased risk of diabetic nephropathy, identification of substances in blood and/or urine that signal high-risk patients, measurements of tubular dysfunction, etc.) of diabetic nephropathy.

When interpreting the results of microalbumin excretion, it is important to exercise some clinical judgement. The upper limit of normal should not be considered as absolute, and common sense must be used in judging borderline cases. Many factors (e.g., exercise, high blood pressure, urinary tract infection, and very poor diabetic control) elevate the urinary albumin excretion rate. If such confounding factors are present, the finding of microalbuminuria does not necessarily imply incipient diabetic nephropathy. Although several authors have suggested that exercise-induced microalbuminuria is a harbinger of diabetic renal disease, there are few experimental data to support this claim. Another concern about the clinical interpretation of microalbuminuria centers on its development during the first 5 years in T1DM patients. In these patients, microalbuminuria is unlikely to have the same ominous prognostic significance as microalbuminuria that occurs 10–15 years after the onset of diabetes. This statement is not applicable to T2DM patients, who may have had their disease for many years before the diagnosis of diabetes was established. The interpretation of microalbuminuria in Caucasian type 2 diabetic patients is further complicated, since approximately 25% of such individuals have microalbuminuria, yet the incidence of renal disease in this popula-

TABLE 43-2. Definition of Microalbuminuria

	Urinary AER (mg/24 h)	Urinary AER (μg/min)	Urine Albumin/ Creatinine (mg/mg)
Normoalbuminuria*	<30	<20	<0.02
Microalbuminuria	30–300	20–200	0.02–0.20
Macroalbuminuria	>300	>200	>0.20

*The mean value for urinary albumin excretion rate (AER) in normal individuals is 10 ± 3 mg/d or 7 ± 2 μg/min.

FIGURE 43-8. Overall survival in 76 T2DM patients with varying degrees of microalbuminuria based upon the urinary albumin concentration. Patients with microalbuminuria in the moderate to high range (**two right bars**) demonstrated a markedly shortened survival compared to an age-matched control population. (Reproduced with permission from Mogensen.⁹⁹)

tion is only 5–10%.^{85,99–101,104} Therefore, although microalbuminuria is a risk factor for the development of renal disease in type 2 diabetics, it is not as strong a predictor as in type 1 diabetics. Thus, type 2 diabetic patients with microalbuminuria have a fivefold increased risk (as opposed to the 20-fold increase seen in T1DM) of developing proteinuria over a 10-year period. However, in certain ethnic populations with a high incidence of diabetic nephropathy and type 2 diabetes, including Native Americans, Mexican-Americans, and African-Americans, microalbuminuria is a very strong predictor of proteinuria and impaired renal function.^{86,103,106}

From the more routine laboratory standpoint, the earliest detectable manifestation of diabetic glomerulosclerosis is Albustix-positive proteinuria (see Fig. 43-3), which begins about 15–18 years after the diagnosis of diabetes.^{55,86,89,95–97,99,103} At this time, the GFR may still be normal or even elevated, but within a mean of 5 years after the onset of this level of proteinuria, the GFR begins to decline, and the serum urea nitrogen and creatinine concentrations increase. Within ~3–5 years after an elevation in serum creatinine concentration is documented, about half of the patients will have progressed to end-stage renal insufficiency. Severe proteinuria (>3 g/d) and the nephrotic syndrome are common, occurring in over half of all diabetic patients who progress to end-stage renal failure.

LABORATORY ABNORMALITIES

Proteinuria

The earliest laboratory manifestation of diabetic renal disease is proteinuria. When the urine albumin excretion exceeds 300 mg/d (corresponding to a urine protein excretion of 500 mg/d), the patient is said to have *overt diabetic nephropathy*. Using fractional dextran clearances and urinary albumin/IgG excretion, the increased transglomerular flux of proteins has been shown to result from an augmented transglomerular ultrafiltration pressure gradient and an alteration in the molecular charge of the glomerular barrier, which results from the loss of anionic charges (heparin sulfate and sialic acid residues) from the GBM.^{56,57,100,103,107,108} Neither the number of pores in the GBM nor the pore size is altered in the course of diabetic nephropathy. At this stage, loss of barrier charge selectivity, without alteration of pore size diameter, appears to be the primary factor that allows the escape of albumin without change in the clearance of other macromolecules, and improved glycemic control with intensive insulin therapy decreases the albumin excretion rate.

rate.¹⁰⁹ More recently, studies by Comper and coworkers^{73,74} have demonstrated an important contributory role for impaired tubular handling of albumin in the development of microalbuminuria. With progressive proteinuria and the development of impaired renal function, glomerular charge- and size-selectivity is lost, there is an increase in pore size with the appearance of large-molecular-weight proteins in the urine, due to enhanced transglomerular passage of plasma proteins.

Glomerular Filtration Rate

Prior to the onset of microalbuminuria, the GFR is increased^{55–57, 85,86,99–104,110,111} as the result of increased intraglomerular pressure and increased glomerular capillary surface area (Fig. 43-9).^{55–57,85} The elevated GFR often persists even though marked renal histologic changes are present. Thus a decline in GFR from elevated to normal values in the absence of an improvement in metabolic control represents an ominous finding (Fig. 43-9). The most commonly used laboratory tests that provide an index of GFR are the serum creatinine and serum urea nitrogen (SUN) concentrations. However, both (especially the SUN) are influenced by prerenal (i.e., extracellular fluid volume depletion) and postrenal (i.e., urinary tract obstruction) factors. The serum creatinine concentration also is dependent on the muscle mass. Consequently, a decrease in muscle mass (as occurs with advancing age) can lead to a reduction in serum creatinine concentration and an underestimation of the severity of renal impairment. More importantly, the GFR may decline by 40–50% before either test increases into the abnormal range. Therefore, many nephrologists and diabetes specialists have advocated serial determinations of the creatinine clearance. In patients with renal failure of diverse etiologies, a plot of the reciprocal of the serum creatinine concentration as a function of time is linear and is useful in following the progression of renal disease. Pragmatically, the author advocates following the creatinine clearance in patients with diabetes with normal serum creatinine levels. Once the serum creatinine concentration becomes elevated, either the reciprocal of the serum creatinine or the creatinine clearance can be followed.

The glomerular filtration rate is determined by two factors: the net transmembrane ultrafiltration pressure and the glomerular ultrafiltration coefficient. The ultrafiltration pressure is governed by the balance of forces between the transmembrane hydraulic pressure, which increases GFR, and the intraglomerular oncotic pressure, which decreases GFR. In animals and man, experimental

FIGURE 43-9. Natural history of glomerular filtration rate (GFR) and urinary albumin excretion rate (AER) in 20 type 1 diabetic patients who progressed to overt diabetic nephropathy over a period of 12 ± 3 years. GFR and AER are shown at the time of initial examination (circles) and after varying periods of follow-up (triangles). Shaded areas show the normal range. (Reproduced with permission from Mogensen.¹³¹)

diabetes elevates the transmembrane ultrafiltration pressure.^{56,100} Because the glomerular capillary oncotic pressure is normal or reduced in patients with diabetic nephropathy, this factor cannot explain the decrease in GFR. By exclusion, therefore, it has been concluded that the glomerular ultrafiltration coefficient must be reduced. The ultrafiltration coefficient is determined by the surface area available for filtration and the hydraulic permeability. Changes in the latter term have not been evaluated. Early in the course of T1DM, the total glomerular capillary surface area is increased and contributes to the glomerular hyperfiltration. However, in diabetic patients with clinically manifest renal disease, the mesangial matrix is greatly expanded, with obliteration of many capillary lumina.⁵ Anatomically, this reduction in surface area for filtration plays a significant role in the decline in GFR in patients with advanced diabetic nephropathy.

Glucosuria

The maximum tubular reabsorptive capacity for glucose (Tm_G) varies inversely with the GFR in healthy individuals, and similar observations have been made in patients with new-onset T2DM.¹¹² However, in patients with long-term diabetes with reduced GFR and diabetic glomerulosclerosis, the Tm_G is raised. Moreover, even in patients with diabetes without renal disease, glucosuria correlates relatively poorly with the plasma glucose concentration.

Hyperkalemia

The maintenance of normal potassium homeostasis depends on both renal and extrarenal mechanisms (Fig. 43-10).¹¹³ Many factors predispose the patient with diabetes to the development of hyperkalemia. Three hormones play a pivotal role in regulating the distribution of potassium between intracellular and extracellular compartments: insulin, epinephrine, and aldosterone. In patients with longstanding diabetes mellitus, all three of these hormones may be deficient. Therefore, it is not surprising that hyperkalemia

is a commonly encountered clinical problem in the diabetic population.¹¹³ Moreover, in poorly controlled patients the elevated plasma glucose concentration increases tonicity, causing an osmotic shift of fluid and electrolytes, primarily potassium, out of cells. Metabolic acidemia, common in patients with diabetes, also predisposes to hyperkalemia. During the development of metabolic acidemia about half of a hydrogen ion load is buffered within cells, and it occurs in exchange for potassium ions.¹¹³

Renal mechanisms also contribute to the development of hyperkalemia. When the GFR declines to less than 15–20 mL/min the ability of the kidney to excrete potassium may become impaired.¹¹³ Essentially, all of the filtered potassium is reabsorbed in the early- to mid-distal tubule, and the potassium that appears in the final urine represents potassium that is secreted by the late distal tubule and collecting duct. Many patients with diabetes demonstrate a marked interstitial nephritis with prominent tubular atrophy and tubular basement membrane thickening.^{14,20,21} Because much urinary potassium is derived from distal and collecting tubular secretion, renal potassium excretion becomes impaired.

Hypoaldosteronism is common in patients with diabetes, particularly in those with evidence of impaired renal function (Fig. 43-10).^{113,114} Since aldosterone is a key regulator of potassium secretion by the distal tubule and collecting duct, aldosterone deficiency results in impaired potassium excretion. Most patients with hypoaldosteronism are asymptomatic and are diagnosed on routine laboratory screening (by the presence of hyperkalemia) or during evaluation for some other, unassociated illness. The baseline plasma aldosterone concentration is low and fails to increase normally after stimulation with volume contraction. In most patients the plasma renin level also is reduced and accounts for the hypoaldosteronism. However, in about 20% of patients with hypoaldosteronism, normal basal renin values have been reported.^{113,114} Moreover, all patients with the syndrome of hyporeninemic hypoaldosteronism have clinically significant hyperkalemia, which is the most potent stimulus to aldosterone secretion. This suggests that, along with hyporeninemia, there may be a primary adrenal

FIGURE 43-10. Hyperkalemia and the renin-angiotensin-aldosterone system. (Reproduced with permission from DeFronzo et al.¹¹³)

fect in aldosterone secretion. This hypothesis is supported by the observation that the aldosterone response to angiotensin II and adrenocorticotrophic hormone, agents that directly stimulate aldosterone secretion by the zona glomerulosa, is markedly impaired in persons with hypoaldosteronism.¹¹³⁻¹¹⁵

The pathogenic factors responsible for the impairment in renin and aldosterone secretion are unknown. Hyporeninemia could result from damage to the juxtaglomerulosa apparatus, impaired conversion of the biologically inactive renin precursor ("big renin") to renin, decreased circulating catecholamine levels or autonomic neuropathy, diminished circulating prostaglandin levels, or chronic extracellular fluid volume expansion secondary to hyperglycemia and sodium retention. However, none of these disturbances can satisfactorily account for the development of hyporeninemia in most diabetics. Impaired aldosterone secretion may be caused by intracellular potassium depletion within the zona glomerulosa of the adrenal gland secondary to insulin deficiency or insulin resistance.^{113,114} Several enzymatic steps involved in aldosterone biosynthesis are known to be potassium-dependent.¹¹³ Disruption of the normal tubuloglomerular feedback mechanisms also may lead to suppressed aldosterone secretion.¹¹³ In diabetic patients with fasting plasma glucose levels in excess of 180 mg/dL, there is a large increase in the filtered load of glucose. The resultant osmotic diuresis impairs sodium and chloride reabsorption by all nephron segments, disrupting the normal tubuloglomerular feedback control mechanism and leading to suppression of renin, and secondarily, aldosterone secretion.

The complexity of the alterations in the renin-aldosterone axis in patients with diabetes is underscored by a report in which the aldosterone axis was characterized in 59 normokalemic patients with diabetes with normal GFR.¹¹⁶ In half of the patients, both the renin and aldosterone responses were normal, 10% of the patients demonstrated diminished aldosterone secretion despite a normal renin response, 20% had impaired renin release with a normal aldosterone response, and 20% manifested impaired secretion of both renin and aldosterone. These results suggest the presence of multiple defects in the renin-aldosterone axis and a multifactorial origin of hyperkalemia.

A number of drugs have been shown to impair aldosterone secretion¹¹³ and, if prescribed for patients with diabetes, require close monitoring of the plasma potassium concentration. Of these medications, the β -blockers and ACE inhibitors are the most widely known. The ACE inhibitors have been advocated for the treatment of diabetic nephropathy. These agents infrequently cause hyperkalemia, and this complication should be monitored closely at the start of therapy.¹¹³ Another widely used class of drugs, the nonsteroidal antiinflammatory prostaglandin inhibitors, causes hyporeninemic hypoaldosteronism and hyperkalemia.¹¹³ The diuretic agents (e.g., spironolactone, triamterene, and amiloride) block potassium secretion by the renal tubular cell¹¹³ and also may result in hyperkalemia.

Metabolic Acidosis

Metabolic acidosis, both anion gap and hyperchloremic (nonanion gap), is commonly observed in patients with diabetes.^{113,114,117} The anion gap is calculated by subtracting the concentrations of the major anions (chloride plus bicarbonate) from the major cation (sodium). The difference should not exceed 12 ± 2 mEq/L. If the value is greater than 14 mEq/L, an anion gap acidosis is present.

There are three possible causes of an *anion gap acidosis*: renal insufficiency, ketoacidosis, and lactic acidosis, and all three may occur in diabetic patients. Ketoacidosis and lactic acidosis are discussed in Chap. 34. In diabetic nephropathy, as in other causes of chronic renal disease, when the GFR declines to 20–25 mL/min, the ability of the kidney to excrete titratable acid becomes impaired, and the laboratory manifestation is an anion gap acidosis.

The causes of an anion gap acidosis are well known to the clinician. Less well recognized is the frequent occurrence of a *hyperchloremic* (or *nonanion gap*) *metabolic acidosis*. The syndrome of hypoaldosteronism is commonly observed in patients with diabetes, particularly those with renal impairment.¹¹³⁻¹¹⁵ Over half of the reported cases of hyporeninemic hypoaldosteronism present with a hyperchloremic metabolic acidosis.¹¹³⁻¹¹⁵ Aldosterone is an important regulator of ammonia production and hydrogen ion secretion by the distal nephron. Ammonium is an important urinary buffer that prevents the urine pH from dropping to very low levels, which would lead to an inhibition of hydrogen ion secretion by the renal tubule. Because of deficient ammonium secretion, the amount of urinary buffer—and therefore the total amount of hydrogen ion that can be secreted—is reduced in patients with diabetes with hypoaldosteronism. Because aldosterone does not affect urinary acidification, urine pH remains acidic (pH < 5.4). Some patients present with a hyperchloremic metabolic acidosis secondary to a primary renal tubular defect in hydrogen secretion. These individuals have a true distal renal tubular acidosis (i.e., an inability to acidify the urine [pH > 5.4] despite systemic acidemia). This defect may be related to the prominent interstitial nephritis, to the tubular basement membrane thickening, or to an intracellular abnormality in any of the steps involved in hydrogen ion secretion. Other patients with diabetes may present with a hyperchloremic metabolic acidosis due to widespread chronic interstitial nephritis and diffuse tubular injury, resulting in decreased ammonia production. The urine pH in these latter individuals is maximally acidic, indicating that the ability of the distal tubule and collecting duct to generate a steep pH gradient is intact. In these patients, the primary problem is impaired ammonia production, leading to a decrease in the total amount of hydrogen ion that can be excreted. In the absence of ammonia, which is one of the major urinary buffers, the urine pH is maximally acidic. Hyperkalemia may also cause a hyperchloremic metabolic acidosis by inhibiting ammonia synthesis by the renal tubular cell.

CLINICAL CORRELATIONS

Diabetic nephropathy is unusual in the absence of retinopathy, neuropathy, and hypertension. These associations were first popularized by Root and colleagues,¹¹⁸ who referred to the triopathy of diabetes: nephropathy, retinopathy, and neuropathy. The occurrence of this triad was supported by other studies.¹¹⁹ However, the validity of this association has also been challenged,¹²⁰ and more recent reviews¹²¹⁻¹²³ suggest a more variable association between the three microvascular complications. Patients with diabetes with nephropathy invariably have retinopathy and the diagnosis of diabetic nephropathy should not be made in the absence of some evidence of retinal involvement. This association has been referred to as the renal-retinal syndrome. However, less than half of the patients with diabetes with retinopathy have clinically evident renal disease. The association between diabetic neuropathy and

retinopathy/nephropathy is even more variable, and is clouded by the fact that uremic neuropathy can occur in absence of diabetes.

Diabetic Retinopathy

Diabetic retinopathy (e.g., hemorrhages, exudates, proliferative retinopathy) invariably is present in patients with diabetes with end-stage renal failure who are admitted into dialysis or transplantation programs.^{123,124} However, when overt diabetic nephropathy is first diagnosed (i.e., documentation of persistent proteinuria or elevation of the serum creatinine concentration), 30–40% of patients do not have evidence of diabetic retinopathy by routine ophthalmologic examination,^{119,120,123,124} even though fluorescein angiography will demonstrate typical diabetic abnormalities in over 80–90% of patients. As the renal disease progresses, however, diabetic retinopathy appears to accelerate.^{122–124} In one study, evidence of retinopathy was noted in only 61 of 150 patients when nephropathy was first diagnosed, but retinal involvement developed in another 42 during the follow-up period.¹²⁵ In patients placed on hemodialysis, a rapid progression of diabetic retinopathy often ensues. A dissociation between retinopathy and nephropathy is evident if one examines patients with established retinopathy. After 15–20 years, over 80% of patients have evidence of diabetic retinopathy, but as many as 30–50% have no laboratory evidence of renal disease.

Diabetic Neuropathy

The association between diabetic nephropathy and neuropathy is much less striking than that between diabetic nephropathy and retinopathy. In patients who have had diabetes for ≥ 20 years, only half exhibit clinical evidence of neuropathic involvement.^{123,126–128} In patients with end-stage renal failure, the incidence of diabetic neuropathy varies from 50–90%, depending upon how carefully one looks or tests for evidence of diabetic neuropathic involvement. Peripheral neuropathy is more evident clinically than autonomic neuropathy, although in a recent study symptomatic diabetic gastroparesis was observed in $\sim 50\%$ of patients with diabetes treated with dialysis.¹²⁹ However, the specificity of these neuropathologic abnormalities, especially those relating to peripheral neuropathy, is questionable because dialysis and transplantation often lead to their reversal,¹³⁰ suggesting a uremic etiology. As with retinopathy, uremia appears to exacerbate the progression of diabetic neuropathy. When diabetic nephropathy is first diagnosed, less than half of patients have clinically evident diabetic neuropathy.

Hypertension

The incidence of hypertension, as well as the relationship between hypertension and renal disease, is very different in patients with T1DM and T2DM. In newly diagnosed type 2 patients, approximately 50–60% have hypertension, whereas less than 10% of type 1 patients present with hypertension at the time of initial diagnosis.^{55,85,89,131–133} In both T1DM and T2DM patients, the incidence and severity of hypertension progress as the proteinuria becomes more severe. When end-stage renal failure ensues, 70–80% of patients with diabetes are hypertensive.¹³⁴ Patients with heavy proteinuria are particularly prone to develop hypertension. In most patients, the hypertension is volume-dependent and becomes easier to control after dialysis is started and dry weight is attained.^{135,136}

Edema

The full-blown Kimmelstiel-Wilson syndrome includes edema, hypertension, proteinuria, and azotemia. In patients without renal disease or in those with mild-moderate proteinuria (<0.5 – 1 g/d) and normal GFR, edema is uncommon. However, when the urinary albumin excretion exceeds 1 – 2 g/d, and especially when the GFR begins to decline, the incidence of edema increases precipitously. This is caused by decreased oncotic pressure secondary to hypoalbuminemia, sodium retention secondary to renal disease, and altered vascular permeability. When end-stage renal failure ensues over 50–75% of patients have some evidence of edema.^{125,137}

TREATMENT OF DIABETIC NEPHROPATHY

The treatment of patients with *established* diabetic nephropathy is aimed at slowing the progressive decline in GFR. Once overt albuminuria (>300 – 500 mg/d) is present and the serum creatinine concentration begins to increase, the progression to end-stage renal disease is difficult to halt (Table 43-3). If end-stage renal failure ensues, two options are available: dialysis or transplantation.

Hypertension

Hypertension, even in its mildest form, is associated with decreased survival in patients without diabetes,¹³⁸ and this effect is magnified in patients with diabetes (see Chap. 48).¹³⁹ Hypertension is the single most important factor that accelerates the progression of diabetic renal disease, and treatment of the hypertension, regardless of the agent employed, markedly slows the progression of renal insufficiency in patients with established renal disease.^{55,134,139–141}

Over 25 years ago, it was demonstrated that antihypertensive therapy reduced albuminuria and slowed the rate of decline in GFR in patients with T1DM with established nephropathy.¹⁴² This initial observation has been confirmed by multiple investigators (Fig. 43-11).^{55,57,85,134,140,141,143–145} Elevated blood pressure interacts synergistically with poor glycemic control, hypercholesterolemia, and microalbuminuria to accelerate the decline in glomerular filtration rate (Fig. 43-12).¹⁴¹ In a long-term, randomized, double-blind, prospective study of 409 type 1 diabetic patients with established nephropathy,¹⁴⁶ it was demonstrated that antihypertensive therapy with captopril decreased the doubling time of serum creatinine by 48% and reduced by 50% the combined end points of death, dialysis, and renal transplantation (Table 43-4).

Simple clinical observations have demonstrated the importance of hemodynamic factors in the development of diabetic nephropathy. In type 1 patients with renal artery stenosis, extensive diabetic glomerulosclerosis occurs in the kidney with the patent renal artery, but the kidney with the stenotic renal artery displays only mild diabetic changes.¹⁴⁷ Similar observations have been reported in diabetic rats with Goldblatt kidney hypertension. Conversely, in diabetic rats, dogs, and humans with a single kidney, there is a marked acceleration of diabetic nephropathy, even though systemic hypertension does not develop.¹⁴⁸ This experimental model emphasizes the role of intrarenal hemodynamic factors in the initiation and progression of diabetic glomerulopathy.^{55,56} In both T1DM and T2DM patients, genetic factors also have been shown to play an important role in the development of hypertension.^{149,150} Hypertension and microalbuminuria also occur as part

TABLE 43-3. Treatment of Diabetic Nephropathy

1. **Hypertension**—the single most important factor shown to accelerate the progression of renal failure.
 - a. Angiotensin converting enzyme (ACE) inhibitors, angiotensin receptor blockers, and calcium channel blockers are efficacious and relatively free of side effects. Hyperkalemia and decreased glomerular filtration rate (GFR) may occur with ACE inhibitors.
 - b. Because of the development of dyslipidemia and insulin resistance, diuretics should not be considered as first-line agents unless used in very low doses; they are, however, indicated in hypertensive patients with evidence of excessive sodium retention, i.e., edema.
 - c. Attempt to avoid propranolol and other β -adrenergic blockers (hyperkalemia, hypoglycemia, hyperglycemia).
2. **Urinary tract infection**—increased incidence, frequent cultures.
3. **Neurogenic bladder**—parasympathetic/adrenergic drugs, voiding maneuvers.
4. **Intravenous pyelography**—increased incidence of acute renal failure, particularly if heavy proteinuria and renal impairment are present.
5. **Blood glucose control**
 - a. Tight blood glucose control, if instituted before or during the phase of microalbuminuria, prevents the development of overt proteinuria and progressive renal failure.
 - b. There is little evidence that tight metabolic control prevents or ameliorates the progression of established renal disease (albumin excretion rate >200 – 300 mg/d or elevated serum creatinine).
 - c. Uremia is associated with insulin resistance and increased insulin requirements.
 - d. With advanced uremia (GFR <15 – 20 mL/min), decreased insulin requirements may be observed because kidney removal of secreted insulin is impaired and hepatic degradation of insulin is inhibited.
 - e. After the institution of dialysis, the situation is complex. Insulin sensitivity improves (hypoglycemia), but the degradation of insulin is enhanced (hyperglycemia); however, most insulin-treated diabetics who are started on dialysis experience an increase in their daily insulin requirement.
6. **Dialysis**
 - a. One in every three patients beginning dialysis in the United States has diabetes.
 - b. Diabetic patients do significantly worse on dialysis than do nondiabetic persons.
 - c. The increased mortality in diabetic patients treated with dialysis is largely due to cardiovascular deaths resulting from myocardial infarction and stroke. Other complications include peripheral vascular disease, infections, psychiatric problems, and progressive retinopathy and neuropathy.
 - d. Diabetic patients treated with peritoneal dialysis appear to do as well as those treated with hemodialysis.
7. **Transplantation**
 - a. If a well-matched, living, related donor can be found, renal transplantation is the preferable mode of therapy in most people with diabetes.
 - b. Survival statistics with kidneys transplanted from a haplotype-identical relative or unrelated donor are similar to those obtained with hemodialysis.
8. **Protein restriction**
 - a. There are good data in animals that show that a low-protein diet slows the progression of diabetic renal disease.
 - b. In small uncontrolled studies in humans, a low-protein diet has been shown to slow the progression of established diabetic renal disease.
 - c. In a large, well-controlled, prospective study, a low-protein diet did not alter the rate of decline in GFR. In this study, the majority of patients were on an antihypertensive agent (ACE inhibitor or calcium channel blocker). It is likely that a low-protein diet has no added beneficial effect beyond that afforded by the ACE inhibitor or a calcium channel blocker.

of the insulin resistance syndrome,^{55,151} which is a common accompaniment in patients with T2DM.

Hypertension markedly accelerates the progression of diabetic nephropathy in both T1DM and T2DM patients.^{134,140,141} Therefore, it is essential that all patients with diabetes have their blood pressure normalized. Even mild hypertension (130/90 mm Hg) should not be tolerated in these patients. The Sixth Report of the

Joint National Committee recommends a blood pressure goal of 130/85 mm Hg in patients with diabetes.¹⁵² This is consistent with the recommendation of the American Diabetes Association. The Hypertension Optimal Treatment (HOT) trial, which compared the achievement of a diastolic blood pressure less than 80 versus <85 and <90 mm Hg, concluded that the optimal blood pressure in patients with diabetes in order to prevent macrovascular complica-

tions should be less than 120–130/80 mm Hg.¹⁵³ The National Kidney Foundation Hypertension and Diabetes Working Group also recommends a diastolic blood pressure of <80–85 mm Hg in patients with diabetes based upon a review of clinical trials relating the achieved blood pressure to decline in GFR (Fig. 43-13).¹³⁴ In the author's opinion, the goal of antihypertensive therapy should be to reduce the blood pressure to what the patient's level was before the onset of hypertension or renal disease. In some cases, this may be lower than 120/80 mm Hg. If the patient's blood pressure

FIGURE 43-13. Relationship between achieved mean arterial blood pressure (MAP) control and the decrease in glomerular filtration rate (GFR) in nine long-term, antihypertensive clinical trials of diabetic ($n = 6$) and nondiabetic ($n = 3$) renal disease. These trials suggest that to maximally preserve renal function, the blood pressure should be reduced to less than 130/85 mm Hg, and ideally to 120/80 mm Hg. (Adapted from Bakris et al.¹³⁴)

before the onset of hypertension or renal impairment is not known, then the goal of 120/80 mm Hg is appropriate. Special care should be taken in normalizing the blood pressure in elderly patients, especially those with underlying cardiovascular disease. Hypertension in patients with diabetes is very volume sensitive. Therefore, a low sodium diet should be used to initiate therapy.^{154,155} The characteristics of the ideal antihypertensive drug for the treatment of hypertension in patients with diabetes is shown in Table 43-5. Because hypertension in these patients is very volume sensitive, diuretics would appear to be a logical first-line choice. However, this class of drugs, particularly at higher doses, may aggravate insulin resistance, impair insulin secretion, and cause dyslipidemia.^{156,157} Because of these adverse effects on glucose tolerance and plasma lipid levels, if thiazide diuretics are to be used as first-line agents in the treatment of the hypertensive diabetic, they should be used in low doses (i.e., less than 25 mg per day of hydrochlorothiazide), and plasma glucose and lipid levels should be monitored closely after institution of therapy.^{149,152,156,157} In patients with edema or renal insufficiency, a diuretic usually is required to normalize the blood pressure. If the serum creatinine concentration is more than 2 mg/dL, a more potent loop diuretic will be required. β -Adrenergic antagonists, especially the nonspecific β -blockers, should be used with caution in diabetic patients. They can impair insulin secretion and worsen glucose tolerance in patients with T2DM. In patients with T1DM, β -blockers may cause hypoglycemia by inhibiting

TABLE 43-5. The Ideal Antihypertensive Drug in Diabetes Mellitus

Is metabolically "neutral" and does not inhibit:

- Insulin secretion
- Insulin action
- Hepatic glucose production
- Counterregulatory hormone release

Does not:

- Cause or mask symptoms of hypoglycemia
- Aggravate dyslipidemia
- Promote orthostatic hypotension
- Aggravate coronary/peripheral vascular disease

Does:

- Specifically preserve renal function

hepatic glucose production and impairing the counterregulatory hormone response to hypoglycemia. β -Blockers may also mask the clinical symptoms of hypoglycemia, and they can aggravate diabetic dyslipidemia and underlying peripheral vascular disease in both type 1 and type 2 patients. Despite these concerns, the results of the UKPDS¹⁵⁸ demonstrated that after 9 years, treatment with atenolol (a selective β_1 -antagonist) was as effective as captopril in reducing overall mortality, macrovascular complications (myocardial infarction, stroke, peripheral vascular disease), and microvascular complications (primarily retinopathy). Dyslipidemia and glycemic control were not aggravated by atenolol. The failure to observe any adverse metabolic effects during atenolol treatment most likely is related to its β_1 selectivity and the low daily dose that was employed.

Elevated intraglomerular pressure is a characteristic feature of the diabetic kidney, and this alteration in renal hemodynamics is in part related to increased sensitivity of the efferent arteriole to angiotensin II.⁵⁶ Consequently, the angiotensin-converting enzyme (ACE) inhibitors have gained widespread acceptance as the drug of choice in the treatment of the hypertensive diabetic, especially if proteinuria or renal insufficiency is present.^{55,57,58,85,90,134,140,144-146,149,154,155}

ACE inhibitors also have been shown to retard the progression of albuminuria and decline in GFR in type 1 (Fig. 43-14) and type 2 (Fig. 43-15) patients with microalbuminuria.^{55,58,85,90,132,144,146,154,155,159-166} Parving^{143,145} has demonstrated a sustained protective effect of captopril in patients with T1DM over a follow-up period of 10 years. In short-term studies the antiproteinuric effect of the angiotensin II receptor blockers and ACE inhibitors has been shown to be similar in patients with and without diabetes with renal disease.¹⁶⁷ An added advantage of the ACE inhibitors is that they may improve insulin sensitivity and may have a beneficial effect on the plasma lipid profile.^{156,157,166}

Most recently, two long-term prospective studies have demonstrated the effectiveness of the angiotensin II receptor blockers losartan and irbesartan in slowing the progression of renal failure in patients with T2DM (Fig. 43-16).¹⁶⁸⁻¹⁷⁰ Some authorities have suggested that the angiotensin receptor blockers may be more effective than the ACE inhibitors, since the latter reduce only ACE-dependent angiotensin II production, whereas the receptor blockers inhibit the effect of angiotensin II from any source. However, the renal protective effects of losartan¹⁶⁹ and irbesartan^{168,170} appear to

FIGURE 43-14. Effect of captopril versus placebo therapy on albumin excretion rate (AER) in 225 type 1 diabetic subjects with microalbuminuria. FIGURE 43-16. Effect of irbesartan versus placebo therapy on albumin excretion rate (AER), creatinine clearance, and mean arterial blood pressure in 395 hypertensive type 2 diabetic patients with microalbuminuria. Thirty of 201 (15%) placebo-treated and 10 of 194 (5%) irbesartan-treated patients progressed to persistent proteinuria over 2 years ($p < 0.001$). (From Parving et al.¹⁷⁰)

be no greater than those of the ACE inhibitors.¹⁴⁶ Moreover, there is experimental evidence to suggest that elevated kinins (not observed with the angiotensin receptor blockers) may be responsible for some of the renal protective effects of the ACE inhibitors.¹⁷¹ The evidence from experimental models of diabetic and nondiabetic renal disease indicates that the ACE inhibitors and angiotensin receptor blockers afford equivalent renal protection despite differences in the site of inhibition of the renin-angiotensin system. Although combination therapy with an ACE inhibitor and an angiotensin receptor blocker has been suggested, there are no long-term data in humans to support such an approach.

The calcium channel blockers and postsynaptic α_1 -adrenergic blockers also effectively lower blood pressure in patients with diabetes, and have been shown to exert a beneficial effect on renal function in patients with proteinuria.^{55,153,154,172-177} Some evidence suggests that an ACE inhibitor plus a calcium channel blocker may provide an additive effect in preventing the progression of renal disease.¹⁷⁸⁻¹⁸⁰ Moreover, when ACE inhibitors are used with calcium channel blockers, this combination has resulted in a reduction in cardiovascular events.^{153,181} The calcium channel blockers have no adverse effects on either glucose or lipid metabolism, while the α -blockers improve insulin insensitivity and promote a less atherogenic plasma lipid profile.^{172,173}

In summary, the ACE inhibitors or angiotensin receptor blockers, along with the calcium channel antagonists and the α -blockers, should be considered the agents of choice in treating the hypertensive diabetic patient. Since the treatment of hypertension is the single most important factor in preventing the progression of diabetic nephropathy,⁵⁵ and since the ACE inhibitors appear to provide a modest additional benefit beyond their antihypertensive action^{134,140,159} by their effects on intrarenal hemodynamics⁵⁶ and nonhemodynamic mechanisms,⁷⁷ it is the author's opinion that the ACE inhibitors are the drugs of choice in treating hypertensive patients with diabetes and evidence of renal disease.

Microalbuminuria

Microalbuminuria (albumin excretion rate of 30–300 mg/d) represents the earliest detectable stage of diabetic nephropathy (Fig. 43-3). Type 1^{55,85,86,105} and type 2^{55,85,86,99-101,105} patients with microalbuminuria have a 20-fold and a 5-fold increased risk, respectively, of developing clinical proteinuria (>300 mg/d of albumin) or diminished GFR within a period of 10 years. Treatment of microalbuminuria with an ACE inhibitor has been shown to significantly reduce the rate of microalbumin excretion and retard the progression of microalbuminuria to clinical proteinuria (albumin excretion rate >300 mg/d) in both type 1 and type 2 patients.^{140,160-162,167,182-192} ACE inhibitors also decrease the incidence of cardiovascular disease in both hypertensive and normotensive individuals with diabetes.^{193,194}

At the time that microalbuminuria is first detected, the blood pressure is normal or only modestly elevated. Therefore, in many patients with diabetes, the treatment of microalbuminuria must focus on reducing the level of albumin excretion and not on lowering the blood pressure. All diabetic patients should have an annual test for microalbuminuria. This can be done using a timed urine collection (e.g., over 24 hours) or by checking the microalbumin:creatinine ratio or microalbumin concentration (Micral Dipstix, Roche Diagnostics) on a first-voided morning urine specimen. If microalbuminuria is detected, the author prefers to base future therapeutic interventions

on the 24-hour microalbumin excretion rate or on the microalbumin:creatinine ratio (Table 2). After quantitating the rate of microalbumin excretion, the patient is started on the ACE inhibitor of choice (e.g., captopril, 12.5 mg three times a day; enalapril, 5 mg/d; monopril, 10 mg/d) and a repeat urine microalbumin determination is performed in 6–8 weeks. If microalbuminuria is diminished but still present, the dose of the ACE inhibitor should be increased (e.g., captopril by 12.5 mg three times a day; enalapril by 5 mg/d; monopril by 10 mg/d) every 6–8 weeks until the microalbuminuria disappears or the microalbumin excretion rate remains unchanged over three successive dose titrations. The ACE inhibitors produce a maximum or near maximum reduction in microalbumin excretion rate within 6–8 weeks. If a beneficial effect of the ACE inhibitor is observed, therapy should be continued for life, since withdrawal of the ACE inhibitor will lead to a return of the microalbuminuria.

Urinary Tract Infection

The incidence of urinary tract infection is increased in patients with diabetes, especially those with glucosuria. High urine glucose concentrations provide an excellent culture medium for bacteria and inhibit WBC function. Therefore, it is important that a urinalysis be performed on each clinic visit. If white blood cells or bacteriuria are noted, a urine culture should be done. Periodic urine cultures should be obtained, and positive cultures should be treated with an appropriate bactericidal antibiotic.

Neurogenic Bladder

Neurogenic bladder is not uncommon in patients with longstanding diabetes, especially in individuals with other evidence of neuropathy. Since the symptoms may be mistaken for prostatic hypertrophy, the clinician must have a high index of suspicion to establish the diagnosis of neurogenic bladder. In addition to the history, repeated bouts of urinary tract infection should provide a clue to the diagnosis. If the presence of a neurogenic bladder is confirmed by cystometrogram, the patient should receive instruction in the Crede manual voiding maneuver, which should be performed every 6–8 hours. Agents such as bethanechol also may be tried. In some patients with diabetes, adrenergic drugs (i.e., phenoxybenzamine) have proven useful. The success of these various medical interventions can be evaluated by determining the postvoid residual volume. If medical therapy proves unsuccessful, intermittent, straight catheterization should be performed at least 2–3 times daily.

Intravenous Pyelography

Diabetic patients are at increased risk to develop acute renal failure after radiocontrast procedures (e.g., arteriography, cholangiography, intravenous and retrograde pyelography, computed tomographic scanning).¹⁹⁵ This adverse event is observed less frequently with the newer contrast agents, but still remains a concern. Patients with impaired renal function (i.e., serum creatinine >2 mg/dL) or heavy proteinuria are at greatest risk. With the judicious use of ultrasound, radionuclide studies, and computed tomographic scanning without contrast, most of the information necessary to ensure adequate diagnosis and treatment can be obtained. If patients with diabetes must receive radiocontrast dye, hydration with normal saline should be started 12–24 hours prior to the procedure.¹⁹⁶

Blood Glucose Control

Glycemic Control

Diabetic nephropathy and other microvascular complications (retinopathy and neuropathy) are reduced in individuals who have maintained a lifetime of near normoglycemia. The product of the mean day-long blood glucose concentration (as reflected by the hemoglobin A_{1c}) and the duration of diabetes provides an index of the total hyperglycemic burden and is the best predictor of microvascular complications.^{111,197} Poor glycemic control is a major risk factor for diabetic nephropathy in both type 1 and type 2 patients.^{55,58,85,123,197,198} and diabetic nephropathy is uncommon when the glycosylated hemoglobin is maintained below 7.0%.^{61,62} In the Diabetes Control and Complications Trial^{35,63} intensive glycemic control with insulin in type 1 patients markedly decreased the risk of microvascular complications (Fig. 43-4). In type 2 patients, improved glycemic control with insulin^{64,65} or oral agents^{65,66} was equally effective in decreasing the risk of microalbuminuria, as well as other microvascular complications. A similar conclusion was reached from the meta-analysis of several smaller clinical studies.⁶⁷ Combined pancreatic and renal transplantation has been shown to prevent the recurrence of diabetic nephropathy in the transplanted kidney as long as the pancreatic transplant functions normally.^{199,200} Conversely, the transplantation of kidneys with established diabetic nephropathy into patients without diabetes leads to a reversal of the renal disease.³⁶ The important role of tight glycemic control in the prevention of diabetic nephropathy has been conclusively established in many animal models of diabetes.^{27-32,201}

Despite the encouraging results observed with intensive insulin therapy in diabetic animal models and from pancreatic transplantation in man and animals, the initiation of tight glycemic control after the onset of overt proteinuria (>300 mg/d of albumin) or renal insufficiency generally has been ineffective in halting the relentless progression to end-stage renal failure in T1DM.^{55,59,60,125,202,203} These findings suggest that intensive glycemic control in humans is most effective when started early,^{25,63-67} i.e., prior to or during the phase of microalbuminuria (30-300 mg/d; see Fig. 43-3) and before the advanced histologic lesions of diabetic nephropathy have become well established. Based upon the available evidence, it is recommended that the hemoglobin A_{1c} in diabetic patients with microalbuminuria and without an elevated creatinine be maintained less than 7% and ideally less than 6% (Table 43-6). In patients with diabetes having normal serum creatinine and albumin excretion rates greater than 300 mg/dL, strict glycemic control (HbA_{1c} <7.0%) is recommended because the level has not been established at which intensified glycemic control of albuminuria is no longer is capable of preventing the progression of renal disease, and because progression of retinopathy and neuropathy still remains a concern. In diabetic patients with renal insufficiency (serum creatinine ≥2.0 mg/dL), a hemoglobin A_{1c} level lower than 7% is desirable, but 7-8% may be acceptable.

Changes in Insulin Degradation and Insulin Sensitivity

In patients without diabetes with renal insufficiency, moderate to severe insulin resistance is a nearly universal finding.²⁰⁴ The defect in insulin action resides in peripheral tissues, primarily muscle.²⁰⁴ Therefore it is not uncommon to observe a deterioration in glycemic control with the advent of renal insufficiency in both type 1 and type 2 patients. However, when the GFR decreases to 15-20 mL/min, both the renal (loss of nephron mass) and hepatic (uremia inhibits insulin degradation by the liver) clearance of insulin become markedly reduced. At this stage, it is common to observe an improvement in glucose tolerance because the insulin, which normally would be degraded by the liver and kidneys, is returned to the systemic circulation. If the insulin (or sulfonylurea) dose is not appropriately reduced, hypoglycemia may ensue and some patients may even cease to require insulin (or sulfonylureas). After the institution of hemodialysis therapy, a complex sequence of events ensues. Dialysis enhances the body's sensitivity to insulin, decreasing insulin requirements.²⁰⁵ However, dialysis also returns hepatic insulin degradation toward normal, increasing the need for insulin.²⁰⁵ Moreover, the stress of dialysis and a tendency for weight gain may increase insulin requirements. In any given uremic patient with diabetes who is started on dialysis, it is difficult to predict what will happen to the insulin requirements. In general, most patients experience an increase in insulin requirements when dialysis is initiated because of the release of insulin-antagonistic hormones in response to fluid shifts.

From the preceding discussion, it is obvious that the physician must be careful in selecting oral hypoglycemic agents for the treatment of patients with diabetes with impaired renal function.²⁰⁶ The ideal oral agent should not enhance insulin secretion, and the metabolism of the oral agent should not be influenced by diminished kidney function. Based upon these theoretical considerations, insulin sensitizers, such as thiazolidinediones (rosiglitazone and pioglitazone) appear to be ideal candidates, but there are no published data with this class of drugs in patients with chronic renal failure. Of interest, troglitazone (which is no longer approved for use as monotherapy because of associated liver toxicity) has been shown to correct albuminuria in streptozocin diabetic rats²⁰⁷ and to halt diabetic glomerulosclerosis by blockade of mesangial expansion.²⁰⁸ Preliminary studies in human T2DM suggest that the thiazolidinediones also can reduce microalbuminuria. Metformin, an insulin sensitizer, is excreted via the kidneys and should not be used if the serum creatinine is greater than 1.4 mg/dL in females or 1.5 mg/dL in males, corresponding to a GFR of ~70 mL/min.²⁰⁹ Accumulation of the biguanide in plasma and tissues may lead to lactic acidosis. Until recently, the only truly short-acting insulin secretagogue was glipizide, which is not available in the U.S. Glipizide is almost entirely metabolized by the liver and its metabolites are inactive.²¹⁰ Therefore it is well suited for use in patients with diabetes with chronic renal failure (CRF). Glimeperide also can be used in CRF patients.²¹¹ Glyburide should be avoided since it has a long half-life,

TABLE 43-6. Recommend Levels of Glycemic Control in Diabetic Individuals

Control	Normal Control	Type 1 Diabetes: Intensive Control	Type 1 Diabetes: Acceptable Control	Type 2 Diabetes: Intensive	Type 2 Diabetes: Acceptable
Premeal blood glucose (mg/dL)	~90	80-120	<140-160	<110	126
Hemoglobin A _{1c} (%)	4.0-6.0	<6.0	<7.0	<6.0	<7.0

and its metabolites have hypoglycemic activity and are excreted in the urine.²¹⁰ Because all sulfonylureas stimulate insulin secretion, titration should be slow (every 2 weeks or more) in patients with CRF. Repaglinide and nateglinide are new nonsulfonylurea insulin secretagogues that belong to the meglitinide class of drugs.²¹² These agents are short acting and must be given 3 times per day before meals. The meglitinides undergo hepatic metabolism to inactive products that are excreted in the bile. Because of these characteristics, the meglitinides are well suited for use in diabetic patients with impaired renal function. Acarbose is not approved for use in patients with diabetes with an elevated serum creatinine. Insulin therapy always remains an option for the treatment of patients with chronic renal insufficiency, but the physician must be aware of the alterations in insulin metabolism discussed above. Although HbA_{1c} levels may be slightly reduced in diabetic patients with advanced renal disease because of shortened red blood cell survival, it remains the best tool for assessing glycemic control in diabetic patients.²¹³

Hypoglycemia in Chronic Renal Failure and Dialysis Patients

Spontaneous hypoglycemia has been reported in patients with CRF with or without diabetes. However, the pathogenic mechanisms responsible for the hypoglycemia have not been elucidated. In insulin-treated type 1 patients, hypoglycemia most commonly results from excessive insulinemia secondary to impaired insulin degradation by the kidneys and the liver. However, in type 2 patients (who are not on insulin or an oral insulin secretagogue) and in patients without diabetes with chronic renal failure, plasma insulin levels are only modestly elevated, and the hyperinsulinemia cannot explain the profound hypoglycemia that has been reported in some patients with chronic renal insufficiency. It is likely that these patients have a defect in hepatic glucose production. Decreased hepatic glucose production secondary to diminished alanine availability for gluconeogenesis has been documented in a single uremic diabetic patient with spontaneous hypoglycemia.²¹⁴ However, the frequency with which decreased alanine availability contributes to spontaneous hypoglycemia is unclear. Severe hypoglycemia also has been reported in patients without diabetes on chronic maintenance hemodialysis²¹⁵ in the absence of malnourishment or elevated plasma insulin levels. Of note, all of these patients were on propranolol. Although propranolol can cause hypoglycemia by inhibiting hepatic glucose production, symptomatic hypoglycemia does occur in hemodialysis patients who are not taking β -adrenergic blocking agents.

Peritoneal Dialysis, Glucose Absorption, and Insulin Requirements

Standard hemodialysate solutions contain no glucose. However, there has been considerable interest in continuous ambulatory peritoneal dialysis (CAPD), especially in patients with diabetes. Because dialysis is performed continuously, and the dialysis fluid contains hypertonic glucose, glucose absorption is considerable. During CAPD in patients without diabetes, plasma glucose levels usually do not rise above 160–180 mg/dL. However, in patients with diabetes who are both insulin resistant and insulin deficient, severe hyperglycemia presents a significant problem with this mode of therapy. To prevent the development of excessive hyperglycemia, insulin is added to the dialysis fluid, and intraperitoneal insulin administration has been employed effectively to achieve excellent glucose control. However, insulin requirements usually are increased two- to fourfold with CAPD. In addition to the increased

glucose load, the presence of obesity and loss of endogenous insulin secretion (which is related to the duration of diabetes) relate closely with the increased insulin requirements in CAPD patients.²¹⁶ It is best to start patients on CAPD in the hospital so that optimal glucose control can be achieved within the short time and without hypoglycemic or hyperglycemic complications.

Protein Restriction

Low-protein diets have been advocated to slow the progression of chronic renal failure.²¹⁷ The use of protein-restricted diets is based on two assumptions: (1) the “adaptive” increases in intraglomerular pressure and renal blood flow that occur after a reduction in renal mass play a pathogenic role in the progressive injury to remaining nephrons, and (2) the “adaptive” changes in renal hemodynamics can be prevented by protein restriction, leading to preservation of renal function.

In both diabetic and nondiabetic rats, when renal mass is reduced by a variety of experimental maneuvers, there is an initial stabilization of renal function which results from an increase in single nephron glomerular plasma flow and intraglomerular pressure. These changes in renal hemodynamics combine to augment the glomerular GFR.²¹⁸ However, on a long-term basis these “adaptive” changes are followed by a progressive decline in GFR secondary to the chronic elevation in intraglomerular pressure, which causes severe glomerular sclerosis and heavy proteinuria. In rats with a single remnant kidney are placed on a low-protein diet, the rises in single-nephron GFR, glomerular plasma flow, and intracapillary hydraulic pressure are prevented, glomerular function markedly improved, and kidney survival is prolonged. Based on these results in animals, a number of studies have examined whether a low-protein diet in humans also will have a palliative effect on the progression of renal failure.^{219–221} Most of these studies were uncontrolled and involved small numbers of patients, few of whom had diabetes. Nonetheless, the results consistently demonstrated that institution of a low-protein diet slowed the decline in GFR in patients with advanced renal failure. More recently, a well-controlled prospective study involving 840 patients with renal disease of diverse etiology has been completed^{222,223} (Fig. 43-17). Insulin-requiring patients with diabetes were not included in the study and diet-treated and sulfonylurea-treated patients were not analyzed separately. After 3 years, no difference in the rate of decline in GFR was observed between the patients receiving

FIGURE 43-17. Effect of low-protein diet on the rate of decline in glomerular filtration rate (GFR) in patients with chronic renal disease of diverse etiology, including T2DM. (Reproduced with permission from Klahr et al.)

the low-protein diet (0.58 g/kg) and those maintained on a normal protein intake (1.3 g/kg). The failure of this large prospective study^{222,223} to demonstrate any beneficial effect of a low-protein diet stands in contrast to many previously published studies with smaller numbers of patients.^{219,221} It is likely that any beneficial effect of the low-protein diet in this large prospective study was obscured by the concomitant use of antihypertensive medications, which were taken by 80% of participants. Moreover, 44% of the study population was taking ACE inhibitors, which have a specific renal protective effect in patients with or without diabetes. Based upon these results, it seems prudent to recommend modest protein restriction (~1.0 g/kg/d) in patients with diabetes who are taking an ACE inhibitor or calcium channel blocker, while reserving more severe protein restriction (0.6 g/kg/d) for patients who are not taking any antihypertensive medications. These severely restricted protein diets are associated with poor patient compliance and require close dietary supervision. If a very low protein diet is used, this can lead to negative nitrogen balance and acceleration of muscle protein breakdown, with the development of clinically manifest myopathy.

Dyslipidemia

Type 2 and poorly controlled type 1 patients with normal renal function commonly have dyslipidemia, characterized by hypertriglyceridemia, reduced HDL cholesterol, small dense LDL particles, and postprandial hyperlipidemia.¹⁵¹ In patients with diabetes and renal insufficiency, the dyslipidemia is aggravated, and in patients with heavy proteinuria, elevated LDL cholesterol and marked hypertriglyceridemia commonly are observed.²²⁴ When patients are started on dialysis, the dyslipidemia usually worsens.²²⁴ Patients with diabetes and impaired renal function are at extremely high risk of developing heart attacks and stroke^{99,101,102,225} (Fig. 43-4), and dyslipidemia represents a major risk factor for cardiovascular disease in this population.^{226,227} The great majority of patients with diabetes on dialysis have some form of dyslipidemia, and cardiovascular disease is epidemic in this group.^{8,228-232} Therefore, it is imperative that all patients with diabetes, whether they have normal renal function, impaired renal function, or are on dialysis, receive aggressive dietary and pharmacologic treatment for their dyslipidemia. The goal of therapy is to reduce the LDL cholesterol and triglycerides to less than 100 mg/dL and 200 mg/dL, respectively. This can be achieved with diet, HMG-CoA reductase inhibitors, and fibric acid derivatives.^{224,233} The HDL cholesterol should be increased to at least 45 mg/dL, but this is often difficult to achieve with pharmacologic therapy. Exercise and the thiazolidinediones (although not approved for this indication) are particularly efficacious in increasing the plasma HDL cholesterol concentration.

Hyperlipidemia has also been implicated as a causative factor in the progression of diabetic nephropathy.²³³⁻²³⁵ In a number of animal models of progressive renal disease, including diabetic nephropathy, lipogenic diets worsen, while cholesterol-lowering medications ameliorate renal injury.²³⁶⁻²³⁸ Although there has been no large interventional study examining the effect of cholesterol reduction on nephropathy, several small, well-controlled studies have been performed. A meta-analysis of these studies²³⁹ demonstrated that reduction of the plasma cholesterol concentration significantly slowed the rate of decline of GFR, regardless of the lipid-lowering agent that was used or the etiology of the renal disease. Thus patients with diabetes should receive aggressive antilipidemic therapy for the prevention of cardiovascular complications and possible protection against progressive renal deterioration.

Dialysis

Once end-stage renal failure occurs, the patient and physician must choose from one of four options: hemodialysis, peritoneal dialysis, CAPD,¹²⁴ or renal transplantation.^{231,240}

One of the most important questions that the physician faces is when to initiate dialysis in the patient with diabetes and advanced renal insufficiency. Vascular access and dialysis should be instituted earlier in patients with diabetes than in those without for many reasons. Once the serum creatinine concentration has increased to 3–4 mg/dL, there is a rapid deterioration in renal function, and most patients with diabetes require dialysis within 6–12 months. In general, patients with diabetes tolerate uremia less well than those without diabetes. In particular, there often is a marked acceleration of diabetic retinopathy and neuropathy. Glycemic control becomes more difficult, and negative nitrogen balance, protein wasting, and myopathy may become significant management problems with advancing uremia. Because of sodium retention, hypertension also becomes more difficult to control. All of these complications are easier to manage if dialysis is instituted early.¹²⁴ Vascular access should be established when the serum creatinine reaches 4–5 mg/dL, and dialysis initiated at creatinine levels of 6–8 mg/dL. Although hemodialysis is the most frequently employed form of dialysis therapy in all patients with end-stage renal failure, it does not appear to be superior to any other dialysis technique. Morbidity and mortality statistics are similar with intermittent peritoneal and chronic ambulatory peritoneal dialysis.^{8,9,229} Regardless of the type of dialysis chosen, survival in patients with diabetes is much worse than in patients without diabetes.^{228,229}

Nutritional management of the patient with diabetes on dialysis requires special attention. Many diabetics are malnourished before starting dialysis, and achieving a positive nitrogen balance may be difficult. Patients should receive 37.5–40 kcal/kg of ideal body weight, with about half of the calories given as carbohydrates, primarily complex ones. The achievement of positive nitrogen balance requires at least 1.5 g/kg/d of high-biologic-value protein. With this intake, most insulin-requiring patients on dialysis require a split, mixed insulin regimen to achieve adequate glucose control. A morning and evening injection of long-acting insulin (i.e., NPH) or a single injection of glargine insulin is usually required. The long-acting insulin should be administered with sufficient quantities of regular or very-rapid-acting insulin to cover the postprandial glucose excursions. After dialysis is initiated, the total daily insulin requirement usually increases by 50–100%.²⁴¹ Because of frequent, unpredictable fluctuations in glucose control, it is essential that patients with diabetes perform home blood glucose monitoring.

Renal Transplantation

Results from the United States Renal Data System^{228,231} indicate that patients with diabetes who are treated by kidney transplantation, especially if the kidney is donated by a living donor, have a much better survival than those who are placed on dialysis. If a human leukocyte antigen (HLA)-identical donor can be found, the chances of long-term patient survival are far superior to those of dialysis. HLA-nonidentical recipients also do better than patients with diabetes treated with dialysis. Long-term survival with cadaveric renal transplantation is slightly better than with dialysis. Therefore, in the absence of an HLA-related donor, the choice between dialysis and transplantation must be individualized for each patient with diabetes. Although combined pancreatic/kidney transplan-

tion is at an early stage, recent results^{242,243} suggest that this newer therapeutic option results in lower mortality than dialysis or kidney transplantation alone for patients with T1DM,^{242,243} and it may be beneficial in preventing the recurrence of diabetic nephropathy in the transplanted kidney (see Chap. 55).³⁷ Newer immunosuppressive regimens may bring further improvements in patient survival after cadaveric renal transplantation.

Pathogenesis of Diabetic Neuropathy

Martin J. Stevens

Irina Obrosova

Rodica Pop-Busui

Douglas A. Greene

Eva L. Feldman

The classical histologic studies of autopsy and nerve biopsy material from patients with diabetic neuropathy have identified lesions involving peripheral nerve axons, Schwann cells, perineurial cells, and endoneurial vascular elements may contribute to the pathogenesis of the most common form of diabetic neuropathy, distal symmetric peripheral polyneuropathy.¹⁻¹⁰

PATHOLOGY

Lesions identified include damage to and loss of large and small myelinated nerve fibers with evidence of wallerian degeneration; segmental and paranodal demyelination; and proliferation of endoneurial connective tissue including thickening and reduplication of the basement membranes of nerve fibers, endoneurial blood vessels, and the perineurium. The proximal-to-distal increase in morphologic abnormalities^{1,11} and the topographic and temporal distribution of neurologic signs and symptoms in the distal symmetric polyneuropathy of diabetes suggest a primary axonopathy preferentially involving longer myelinated axons.^{10,12-15} Nerve biopsies from young diabetic patients characteristically exhibit ultrastructural lesions most consistent with an early primary distal axonal atrophy and degeneration.^{8,10,16} However, studies of sural nerve biopsies by Thomas and Lascelles^{3,17} and others^{7,9} and autopsy studies⁶ have emphasized segmental demyelination and remyelination in diabetic distal symmetric polyneuropathy, postulating a primary abnormality of Schwann cells.

Diabetic polyneuropathy may also be characterized by defective axonal regeneration,¹⁸⁻²¹ which has been reported to be both positively¹⁸ and negatively²⁰ correlated with the degree of nerve fiber loss. Progression of diabetic polyneuropathy has been associated with preferential loss of small (<5 μ m) myelinated fibers, which may be most sensitive to glucose toxicity.²² Endoneurial vascular abnormalities such as basement membrane thickening and reduplication, endothelial cell swelling and proliferation, and platelet aggregation resulting in vessel occlusion have been noted in sural nerve biopsies^{4,23} and at autopsy^{2,5,11,24,25} of diabetic patients. A quantitative increase in these vascular abnormalities in association with focal loss of myelinated fibers in older diabetic sub-

jects has been interpreted to suggest hypoxic or ischemic to nerve fibers in diabetic subjects.^{1,4,23} Thus, while demonstrating that most tissue elements of peripheral nerve are involved in the disease process at some point, existing studies of human distal symmetric polyneuropathy provide no consistent evidence as to the location of the initial inciting event.

The neuropathology of diabetic autonomic neuropathy has been less well studied, in part because biopsy material is not readily available. A few reported autopsy studies have demonstrated axonal degenerative changes and fiber loss in the parasympathetic chain,¹³ the vagus nerve, the esophageal and gastric nerves,^{10,14,15} and the intrinsic nerves of the bladder. Vacuolization of autonomic ganglionic neurons has also been described.^{10,14,15}

Relationship of Neuropathy to the Duration and Metabolic Severity of Diabetes in Humans

The relationship of diabetic neuropathy to the severity and duration of hyperglycemia and associated metabolic derangements is an important therapeutic as well as pathogenetic implication. A link between the severity and/or duration of hyperglycemia and development of diabetic neuropathy would support intensive metabolic control as a potential preventive measure and would implicate glucose- or insulin-related metabolic factors as important pathogenetic elements in the disease process. The Diabetes Control and Complications Trial (DCCT) has provided strong evidence of the importance of insulin deficiency, hyperglycemia, or both in the pathogenesis of diabetic neuropathy.²⁶ After 5 years, intensive diabetes treatment designed to lower blood glucose to as close to normal range as possible in nonneuropathic subjects with type 1 diabetes mellitus (T1DM) was able to reduce the prevalence of clinical diabetic neuropathy confirmed by abnormal nerve conduction or autonomic function by 60%.

Pirart's²⁷ 25-year prospective study of 4400 unselected patients in a diabetic clinic probably provides the most convincing epidemiologic link between the duration and severity of diabetes and the presence of clinical neuropathy in patients. Neuropathy, defined as loss of Achilles and/or

reflexes combined with diminished vibratory sensation in the presence or absence of "more dramatic polyneuropathy or mono- or multi-neuropathy," was present in 12% of patients when diabetes was diagnosed, with onset of neuropathy tending to cluster in older type 2 diabetic mellitus (T2DM) patients, in whom antecedent undiagnosed hyperglycemia is difficult to exclude. Thereafter, the cumulative prevalence of neuropathy increased linearly with duration of diabetes to nearly 50% after 25 years.^{27,28}

The prevalence of neuropathy corrected for duration of diabetes did not differ substantially as a function of age at time of diagnosis,²⁷ suggesting that the development of neuropathy is similar in T1DM and T2DM despite fundamental differences in the pathogenesis of the underlying metabolic abnormality. On the other hand, the cumulative prevalence of neuropathy increased with duration of diabetes much more rapidly and attained a much higher prevalence in patients whose diabetes was poorly controlled compared with those whose diabetes was moderately or well controlled.²⁷ Since diabetic neuropathy also occurs in secondary forms of diabetes (pancreatectomy, nonalcoholic pancreatitis, and hemochromatosis),²⁹ neuropathy would appear to be unrelated to the underlying pathogenetic mechanism(s) of diabetes but would instead constitute a concomitant or consequence of the diabetic state as defined by hyperglycemia. Thus the preventive effect of intensive insulin therapy on neuropathy in T1DM established in the DCCT²⁶ would be expected to extend to T2DM as well. Indeed, in the United Kingdom Prospective Diabetes Study (UKPDS), intensified diabetes control was associated with less severe deficits of vibration perception threshold after 15 years.³⁰

The prevalence of diabetic neuropathy, although initially low, increases progressively with duration and severity of insulin deficiency and hyperglycemia.^{27,28,31} However, the relationship between immediately antecedent blood glucose control and the development of diabetic clinical neuropathy is more controversial. The appearance of clinically overt diabetic neuropathy clearly does not uniformly follow a prolonged period of unambiguous severe insulin deficiency and hyperglycemia.³² Since the development of clinically overt neuropathy merely represents a progression from long-standing underlying subclinical neuropathy, temporal dissociation between the momentary quality of glucose control and the development of clinical signs and symptoms of neuropathy is not entirely unexpected. As mentioned above, neuropathic symptoms and signs in newly diagnosed diabetes are usually confined to T2DM, in which the duration of antecedent occult hyperglycemia may be prolonged.²⁷ The sometimes reported "paradoxical precipitation of neuropathy following institution of good control"³² refers primarily to the acute onset of painful neuropathic symptoms that may as likely reflect repair and regeneration of damaged nerve fibers as disease progression.^{24,33} Therefore, despite the close epidemiologic association between clinical neuropathy and the duration and severity of hyperglycemia in populations of diabetic patients,^{27,31,34} the onset of clinically overt diabetic neuropathy in an individual patient is an unpredictable event, neither necessarily reflecting concurrent metabolic control³⁵ nor following inexorably from prolonged and severe hyperglycemia.²⁷

This somewhat loose clinical association can be understood in terms of the indolent and occult nature of the underlying subclinical nerve damage, but it also may indicate the presence of other independent pathogenetic variables such as genetic, nutritional, toxic (e.g., alcohol³⁶), and mechanical (entrapment and compression³¹) factors that may influence the appearance of clinical signs and symptoms in individual patients. Unfortunately, clinical neuro-

pathy was not reassessed in the DCCT until the fifth year after initiation of intensive diabetes therapy, so that the temporal association between the institution of diabetes control and the development of neuropathy could not be determined.²⁶

A characteristic neurophysiologic defect in diabetes is slowing of motor and sensory nerve conduction velocity (NCV), which can be attributed to several types of physiologic and anatomic abnormalities. Maximum NCV primarily reflects the integrity of the largest and most rapidly conducting myelinated nerve fibers; it is only modestly decreased with the selective loss of the largest myelinated fibers since smaller fibers conduct only slightly more slowly; on the other hand, conduction is markedly slowed with widespread demyelination.³⁷ Patients with long-standing, established diabetes exhibit consistent but mild evidence of motor and sensory conduction slowing, whereas patients with clinically overt diabetic neuropathy have slightly more severe electrophysiologic abnormalities than patients with subclinical neuropathy.³⁸ Motor nerve conduction velocity (MNCV) is slightly reduced at diagnosis of T1DM, but it improves rapidly with and declines rapidly without insulin replacement therapy in a pattern consistent with an initial, direct, and reversible metabolic contribution to motor conduction slowing in newly diagnosed diabetes.^{39,40} An initial improvement in motor conduction velocity is accompanied by improved vibratory perception threshold, implying a physiologic significance for this reversible functional defect and evidence that both sensory and motor fibers are involved.⁴¹ Nerve conduction velocity slows progressively but modestly in both T1DM and T2DM as a function of duration of disease.^{42,43} In patients with overt diabetic neuropathy, slowing of sensory conduction velocity correlates closely with loss of the largest myelinated fibers, with only a small residual component of conduction slowing attributable to other factors, for example, "metabolic" factors (or possible undetected demyelination).⁵ Nerve conduction velocity inversely correlates with the degree of hyperglycemia as measured by the percentage of glycosylated hemoglobin (HbA_{1c}).⁴⁴

Because the preponderance of conduction slowing in clinically established (and most likely also chronic subclinical) diabetic neuropathy can be accounted for by poorly reversible loss of large myelinated fibers, improvement of NCV following acute metabolic correction is necessarily confined to that small component of conduction slowing not attributed to nerve fiber loss.³¹ Motor conduction velocity improves slightly but proportionately with HbA_{1c} in response to metabolic therapy in chronic stable T2DM.⁴⁵ Similarly, intensified insulin treatment that attains near-normoglycemia significantly improves but does not normalize peripheral NCV in T1DM.⁴⁶⁻⁴⁸ Although consistent with a direct metabolic affect on nerve conduction slowing in established diabetes, these responses, extending over several weeks to months, do not preclude significant structural repair of damaged nerve fibers.

Rapid effects of acute blood glucose normalization on nerve conduction do indeed suggest a small but direct metabolic contribution to nerve conduction slowing in human diabetes. Gallai and associates⁴⁹ studied motor and sensory conduction velocities in multiple peripheral nerves in 16 diabetic patients, 8 with and 8 without clinical neuropathy, before and after 3 days of treatment with a microprocessor-controlled "artificial pancreas," the Biostator™. Conduction velocity improved in peroneal and tibial motor and median sensory nerves, but only in those patients with clinical neuropathy. Service and coworkers⁵⁰ studied eight hyperglycemic subjects with T1DM before and after 72 hours of Biostator regulation and found improvement in ulnar sensory conduction velocity

($+3.2 \pm 1.4$ m/s) but not in 24 other electrophysiologic parameters measured; they concluded that no consistent improvement in nerve function was demonstrable. Troni and coworkers⁵¹ studied H-reflex conduction velocity (n-HCV; a parameter with less day-to-day variation than standard nerve conduction) in subjects with short-duration T1DM before and during 2 days of Biostator glucoregulation. Reduced n-HCV was increased from 1 to 3 m/s after 48 hours of Biostator treatment and also increased progressively over 6 months of intensive insulin therapy in other subjects with T1DM in conjunction with improvement in HbA_{1c}.

These observations suggest that a portion of nerve conduction slowing in diabetic patients is rapidly reversible with metabolic therapy and therefore probably reflects a direct biochemical or biophysical contribution related to metabolic abnormalities in peripheral nerve rather than structural abnormalities. Hence, the nerve conduction impairment in diabetes probably reflects the combined effects of rapidly reversible biochemical and somewhat less readily reversible structural abnormalities in peripheral nerve that cannot be easily distinguished by standard electrophysiologic techniques.

Although conduction slowing is usually more pronounced in diabetic patients with clinically overt neuropathy, the predictive value of conduction impairment for either the subsequent development or clinical course of clinical diabetic neuropathy has not been established.⁵² Therefore, the promising observation that metabolic intervention rapidly improves nerve conduction in diabetic patients does not constitute evidence that such treatment will prevent or ameliorate the subsequent development of diabetic neuropathy. However, intensive diabetes therapy in the DCCT that prevented the development of neuropathy after 5 years was associated with a demonstrable increase in NCV at 1 year (DCCT Study Group, personal communication).

Clinical improvement in overt diabetic neuropathy following institution of improved metabolic control by intensive insulin therapy⁵² would suggest a continuing role for the altered nerve metabolism in established diabetic neuropathy. Although such improvement has been anecdotally reported, appropriately controlled studies that include untreated age- and sex-matched patients with similar type and duration of diabetic neuropathy are not available to confirm the validity of these clinical impressions. Controlled randomized prospective clinical trials comparing treatment strategies that do and do not consistently and predictably lower blood glucose using endpoints that reliably chart the progression of clinically relevant nerve disease are required to establish the efficacy of metabolic therapy in the prevention and treatment of diabetic neuropathy.

Two pilot studies for long-term, randomized controlled prospective intervention trials offered promising results. Holman and colleagues⁴⁶ studied 74 T1DM subjects randomly assigned to "usual" or "intensified" insulin and dietary therapy for 24 months. The HbA_{1c} was significantly lowered by intensive insulin therapy. Vibratory sensory threshold over both lateral malleoli and the medial border of the distal phalanx of both great toes was assessed at baseline and yearly thereafter with a biothesiometer. At the completion of the trial, mean vibratory threshold had worsened in the conventionally treated group and improved in the intensively treated group. The authors therefore concluded that intensive insulin therapy prevented deterioration of vibratory sensation that otherwise occurs in subjects with T1DM on conventional insulin therapy. Service and coworkers⁴⁷ studied T1DM subjects randomly assigned to either conventional treatment or therapy using continuous subcutaneous insulin infusion (CSII) with an insulin pump. By

8 months, statistically significant differences in nerve conduction and vibratory threshold were found favoring the CSII-treatment groups, supporting the observations of Holman and associates.⁴⁴ Increasing vibratory perception threshold and/or slowed nerve conduction are true harbingers of clinically overt neuropathy, thus long-term intensive insulin therapy should delay or prevent the development of diabetic neuropathy.

More definitive data were provided by the large-scale DCCT. This trial studied the prevalence of clinical diabetic neuropathy confirmed by abnormal nerve conduction or autonomic testing in T1DM subjects randomly assigned to intensive versus conventional diabetes therapy for 5 years. Intensive therapy decreased the risk of development of confirmed clinical neuropathy (diagnosed by neurologic history and physical examination and confirmed by nerve conduction or autonomic function studies) at year 5 by 69% (from 9.8% to 3.1% in the primary prevention cohort) and 57% (from 16.1% to 7.0% in the secondary intervention cohort), with an overall risk reduction of 60%.⁵³ The DCCT was not designed to test the efficacy of intensive therapy in the treatment of diabetic neuropathy, and patients with clinically significant diabetic neuropathy were excluded from the study. However, 450 patients at baseline had at least one abnormality on clinical examination and were defined as having "possible or definite" clinical neuropathy. The frequency of abnormal nerve conduction was roughly twice as great in patients with possible or definite neuropathy compared with those without neuropathy. The likelihood of having abnormal nerve conduction was significantly reduced in patients with possible or definite neuropathy treated with intensive (37%) versus conventional (56%) therapy at 5 years ($p < 0.001$). Thus, although not designed to examine the question directly, the DCCT is consistent with the belief that intensive diabetes treatment may benefit patients with existing diabetic neuropathy, at least in its very earliest stage.

The results of the DCCT clearly implicate hyperglycemia and related metabolic abnormalities as overriding factors in the development of clinical neuropathy in T1DM. The similar temporal, anatomic, and clinical characteristics of polyneuropathy in T1DM and T2DM would make extrapolation of this conclusion to T2DM not unreasonable. These results unequivocally implicate metabolic abnormalities associated with insulin deficiency and/or hyperglycemia in the pathogenesis of diabetic polyneuropathy in patients with T1DM.

Glucose Control and Diabetic Autonomic Neuropathy

A beneficial effect of metabolic control on the development or progression of cardiovascular diabetic autonomic neuropathy (DAN) should significantly improve the overall prognosis for diabetes. The relationship of metabolic control to progression of abnormalities of autonomic function has been unclear. Improved metabolic control has been reported to slow the progression of heart rate variability (HRV) deficits in T1DM patients in some studies^{26,53-55} but not in others.^{56,57} As described above, in the DCCT, intensive therapy was able to slow the progression and development of abnormal autonomic tests.⁵⁸ The variability of the reported beneficial effects of good glycemic control on the development or progression of DAN could reflect a number of factors including inadequacy of glycemic control, insufficient study duration, too advanced DAN, or insensitivity of the cardiovascular autonomic function tests utilized.

Direct assessment of cardiac sympathetic integrity has become possible with the introduction of radiolabeled analogs of norepinephrine, which are actively taken up by the sympathetic nerve terminals of the heart.⁵⁹⁻⁶⁴ Quantitative scintigraphic assessment of the pattern of sympathetic innervation of the human heart is possible with either [¹²³I] metaiodobenzylguanidine (MIBG) or [¹¹C] hydroxyephedrine (HED), which may offer greater sensitivity to detect subtle degrees of DAN than is possible by reflex testing. In cross-sectional studies, for example, deficits of left ventricular (LV) [¹²³I] MIBG and [¹¹C] HED retention have been identified in diabetic subjects without abnormalities on cardiovascular reflex testing^{61,63} and have been reported even in newly diagnosed diabetes.⁶² Widespread abnormalities of myocardial LV MIBG uptake have been reported in metabolically compromised newly diagnosed IDDM subjects; these are partially correctable by intensive insulin therapy⁶² and appear to be indicative of a hyperglycemia- or insulin deficiency-induced acute neuronal dysfunction. Recent scintigraphic studies have shown that poor glycemic control has been shown to result in progression of LV sympathetic dysinnervation, which can be prevented⁶⁴ or reversed⁶⁵ by the institution of near-euglycemia. Thus quantitative scintigraphic imaging techniques such as HED positron emission tomography (PET) and MIBG single-photon emission computed tomography (SPECT) have confirmed the importance of glycemic control in the development, progression, or reversal of myocardial sympathetic dysinnervation.

ANIMAL MODELS OF DIABETIC NEUROPATHY

Studies in a wide range of diabetic animal models also firmly implicate insulin deficiency and/or hyperglycemia in the genesis of biochemical, functional, and structural abnormalities in peripheral nerve that seem to parallel at least the early stages of the development of human diabetic peripheral nerve disease. The first experimental evidence of diabetic neuropathy was the demonstration of acute nerve conduction slowing in alloxan-diabetic rats by Eliasson.⁶⁶ Other investigators soon suggested that impaired NCV in rats with experimental diabetes could be improved by insulin treatment.⁶⁷ Diabetic animal models have since served as invaluable tools with which to explore relationships among metabolic and microvascular abnormalities, functional deficits, and neuroanatomic changes under strict experimental conditions (Table 44-1). These models can be separated into those in which diabetes is induced by chemical agents cytotoxic to pancreatic β cells (streptozocin and alloxan), and those in which diabetes occurs spontaneously, sec-

ondary to genetic mutations (the BB rat, db/db mouse, and Chinese hamster). Both alloxan- and streptozocin-induced diabetes in animals, particularly streptozocin-diabetic (STZ-D) rats, have contributed enormously to our understanding of metabolic events in the diabetic nerve. Alloxan or streptozocin diabetes simulates that seen in insulin-dependent diabetes in humans with respect to the pancreatic β -cell destruction.

Hyperglycemia, the principal clinical finding signifying diabetes mellitus, is thought to be an initiating etiologic event in several complications of diabetes. Because galactose intoxication can produce hyperglycemia (albeit with a different sugar) without a significant hypoinsulinemia, it has been used to assess the role of hyperglycemia *per se* in the pathogenesis of diabetic complications.

Diminished Nerve Conduction Velocity in Diabetic Animal Models

The slowing of NCV in the alloxan-diabetic rat initiated the use of experimentally and spontaneously diabetic rodents in the study of the pathogenesis of diabetic neuropathy. Nerve conduction velocity has subsequently been measured in many animal models of diabetes and is generally found to be decreased.⁶⁸⁻⁷⁰ The factors influencing the development of impaired sciatic motor NCV in acutely diabetic streptozocin rats were originally investigated by Greene and coworkers.⁷¹ They showed that decreased MNCV in surgically exposed temperature-controlled sciatic nerve developed 2 weeks after streptozocin administration, but only in animals that became hyperglycemic. Insulin treatment prevented impaired MNCV in diabetic animals.⁷¹ These studies were the first to establish conclusively that insulin deficiency, hyperglycemia, or both are primary factors in the development of impaired MNCV in acute experimental diabetes. Subsequent studies in the acutely streptozocin-diabetic rat, the BB rat, and the db/db mouse have confirmed the initial findings by Greene and coworkers.^{69,70,72,73}

The evidence that the slowing of nerve conduction in acute experimental diabetes results from metabolic alterations caused by insulin deficiency and hyperglycemia⁷³ is readily reversible with metabolic (and or nerve perfusion) correction⁷³ and occurs in the absence of widespread evidence of structural defects such as demyelination, axonal atrophy, or axonal degeneration⁷⁴ or contributory vascular abnormalities⁷⁵ prompted a search for an underlying biophysical/metabolic mechanism. As discussed below, endoneurial hypoxia, oxidative stress, nerve energy deficits, decreased (Na,K)-ATPase activity, and impaired neurotrophism have emerged as critical mediators of hyperglycemia-induced nerve damage.⁷³

TABLE 44-1. Putative Metabolic Initiators and Physiologic Mediators of Glucose Toxicity in Experimental Diabetic Neuropathy

Metabolic Initiator	Tissue Compartment	Physiologic Mediator
Nonenzymatic glycation	Endoneurial microcirculation	Interruption of nerve blood flow
Sorbitol pathway	Perineurial/epineurial vessels	Mitochondrial dysfunction
Glucose auto-oxidation	Dorsal root/anterior horn neurons	Reduced neurotrophic support
Protein kinase C activation	Myelinated/unmyelinated axons	Osmolyte derangements
	Schwann cells	
	Perineurial cells	
	Distal motor/sensory projections

The Biochemical Pathobiology and Pathophysiology of Diabetic Peripheral Nerve

The observations that the severity of hyperglycemia is a risk factor for the development of neuropathy, that more vigorous metabolic treatment prevents or delays neuropathy²⁶ and improves nerve function in diabetic subjects, and that hyperglycemia and its metabolic consequences have been linked to abnormal nerve function and biochemistry in laboratory animals have led to a search for possible biochemical mechanisms by which insulin deficiency and/or hyperglycemia might adversely affect peripheral nerve.

Insulin-deficient diabetic subjects exhibit impaired nerve conduction, which is rapidly reversed by insulin replacement.^{39,40,51} The rapidity with which metabolic intervention improves nerve conduction in insulin-deficient diabetic subjects^{46,47,76} would strongly suggest that a component of nerve conduction slowing in diabetic patients probably reflects a direct biochemical or biophysical contribution related to metabolic factors rather than structural abnormalities. As discussed previously, the analogous rapidly reversible nerve conduction slowing in acutely diabetic animals occurs without fixed alterations of peripheral nerve structure. Therefore, early and reversible slowing of nerve conduction in animal diabetes has been attributed to acute metabolic disturbances that occur in axons, Schwann cells, endoneurial microvessels, and/or their endoneurial environment⁷⁷ as a consequence of acute insulin deficiency.^{71,78,79} Detailed analysis of the biochemical factors contributing to the acutely reversible slowing of nerve conduction in short-term diabetic animals was viewed as a productive point to initiate studies to identify factors that might contribute to the pathogenesis of diabetic neuropathy. At present, there are six distinct but not mutually exclusive and possibly interrelated hypotheses for the pathogenesis of diabetic neuropathy: the sorbitol, hypoxia-ischemia, nonenzymatic

glycation, oxidative stress, apoptosis, and altered neurotrophin hypotheses.

Altered Nerve Metabolism in Acutely Diabetic Rodents

The so-called metabolic hypotheses of diabetic neuropathy argue that metabolic derangements induced by hyperglycemia, insulin deficiency, or both in one or more of the cellular components of peripheral nerve, over time, contribute to progressive functional and structural defects that ultimately culminate in sufficiently severe nerve damage as to produce clinically detectable neurologic deficits. Exploration of the acute effects of diabetes on nerve metabolism and function would constitute a logical venue for the development of specific pathogenetic hypotheses for the disease process. Multiple metabolic and pharmacologic manipulations have recently been shown to modulate the slowing of NCV, reduction of nerve blood flow, resistance of nerve impulse conduction to ischemia, and impaired axonal transport in the acutely diabetic rodent (Table 44-2).^{73,80,81} Each of these invokes a distinct pathogenetic hypothesis for diabetic neuropathy,^{73,81-83} most of which involve alterations in nerve energy metabolism.

Nerve Fuel and Energy Metabolism

Peripheral nerve metabolism shares many characteristics with the central nervous system (CNS).⁸¹⁻⁸³ Glucose entry into peripheral nerve and brain is neither directly regulated by insulin nor rate-limiting for glucose oxidation (its major metabolic fate),^{33,84} so that insulin deficiency should not directly deprive peripheral nerve of adequate metabolic substrate nor should hyperglycemia directly stimulate glycolytic flux by mass action. Glucose uptake

into the sciatic nerve of STZ-D rats has been reported to be decreased,⁸³ which perhaps reflects posttranslational modification of the principal glucose transporters in sciatic nerve, GLUT-1 and GLUT-3.⁸⁵ Nerve adenosine triphosphate (ATP) concentrations have been reported to be unchanged in diabetic rats, and phosphocreatine (PCr) concentrations and PCr:creatine (Cr; a highly sensitive parameter of peripheral nerve energy state)^{86,87} ratios reduced in diabetic rats. The decrease in cytoplasmic high-energy phosphate stores parallels the reduction of endoneurial blood flow and endoneurial hypoxia⁸⁷ and is sensitive to vasodilator therapy, which corrects these deficits.⁸⁸ A report of increased rather than decreased nerve high-energy phosphate compounds in STZ-D rats⁸⁹ may be explained by the use of slow-acting systemic anesthesia for such tissue sampling, since increased metabolic substrate for, and adaptation to, anaerobic metabolism may render diabetic nerve more resistant to the bioenergetic effects of anesthetic hypoxia and/or ischemia.⁹⁰ β -Hydroxybutyrate, but not long-chain fatty acids, serve as major alternative energy substrates.^{33,84} The metabolic role of amino acid oxidation is unclear, although amino acid transport but not content is impaired in diabetic rabbit nerve.⁹¹ On the other hand, carbohydrate metabolism is deranged in diabetic nerve, largely through stimulation of the aldose reductase (AR) or "polyol" pathway, the effect of which has been explored by using specific aldose reductase inhibitors (ARIs) as metabolic probes.

Aldose Reductase and the Sorbitol Pathway

Recent evidence has served to reinforce the link between increased sorbitol pathway flux and the presence of diabetic complications^{92,93} including severe neuropathy.⁹⁴ The concept that aberrant overexpression of the AR gene may predispose to the development of microvascular complications has received support by the identification of polymorphisms at the 5' end of the AR gene that are strongly associated with the presence of neuropathy in diabetic subjects.⁹⁵

Two distinct (but not mutually exclusive) biochemical consequences of increased metabolic flux of glucose through the sorbitol pathway have been invoked to explain the short-term and long-term deleterious effects of hyperglycemia on diabetic nerve and other complication-prone tissues. These are the osmoregulatory consequences of sorbitol accumulation (the *osmotic* or *compatible osmolyte hypothesis*)⁹⁶ and the effect of the sorbitol pathway on the NADH/NAD and NADPH/NADP redox couples linked, respectively, to sorbitol dehydrogenase (SDH) and AR (the *redox hypothesis*).⁹⁷ Studies with specific ARIs strongly implicate this metabolic pathway in the pathogenesis of diabetic peripheral neuropathy (DPN; and perhaps other diabetic complications).^{21,22} In experimental diabetic neuropathy in the rat, ARIs prevent, reverse, or moderate various defects in NCV^{73,80,81,98–100} and ameliorate nerve fiber damage and loss.⁹⁹ In diabetic patients with DPN, potent ARIs improve NCV.^{21,22} In multicenter placebo-controlled clinical trials in patients with DPN, doses of potent ARIs that lower sural nerve sorbitol content by 80–85% also reverse the histologic loss of myelinated sensory nerve fibers.²² The yearly improvements in NCV and myelinated nerve fiber density (MNFD) with effective ARI treatment exceed the magnitude of the yearly loss of MNFD and NCV in untreated diabetic subjects, and they approximate the magnitude of change deemed clinically evident and significant.

The precise mechanisms and the critical loci at which the beneficial effects of ARIs are achieved remain controversial. ARIs cor-

rect many fundamental deficits in experimental diabetic neuropathy (EDN), including impaired axonal transport,¹⁰¹ decreased neurotrophism,^{102,103} nerve osmolyte depletion,^{73,100} redox disturbances,¹⁰⁴ increased oxidative stress,^{73,105} activation of protein kinase c (PKC),^{106,107} depressed nerve (Na,K)-ATPase activity,^{73,108} depletion of vasoactive agents,¹⁰⁹ and nerve blood flow deficits.^{109,110} Osmolyte disturbance secondary to sorbitol accumulation and compensatory depletion of taurine and myoinositol (MI) comprise only one limb of AR pathway effects. Redox disturbances resulting from shifts in adenine nucleotide cofactor couples, and nonenzymatic glycation/glycoxidation resulting from fructose production comprise the two other principal pathogenetic pathways that may contribute to the deleterious effects of AR pathway activation.

The Sorbitol-Osmotic Hypothesis

Kinoshita's¹¹¹ classical osmotic hypothesis of diabetic complications invoked cell "swelling," particularly in the ocular lens exposed to hyperglycemia, as the direct osmotic consequence of intracellular sorbitol accumulation. A modern revision of the osmotic hypothesis identifies sorbitol as one of a class of nonionic, nonperturbing, "compatible" intracellular osmolytes that include MI, taurine, betaine, and glycerophosphorylcholine.⁹⁶ These osmolytes are thought to buffer the cell physiologically against extreme osmotic stress, such as that normally encountered during antidiuresis in the renal medulla. Nonmedullary and even nonrenal cells exposed to hypertonicity exhibit the same compensatory mechanisms even though they rarely if ever encounter such stress *in vivo*. Under hypertonic stress, these compatible osmolytes accumulate intracellularly in a carefully balanced and regulated compensatory fashion through the induction of relevant genes such as AR, the Na-MI and Na-aurine cotransporters, and others.¹¹²

Osmotic induction of these genes is widespread and may occur in response to much smaller osmotic shifts than previously suspected. Hyperglycemia-induced isotonic sorbitol accumulation is unaccompanied by osmotic induction of other osmoreponsive genes.^{113,114} Indeed, the subtle osmotic effects of intracellular sorbitol accumulation (producing a "relative" extracellular hypotonic state) are thought to downregulate the other Na⁺-osmolyte cotransporters.^{100,115} Osmoregulatory genes are transcriptionally upregulated¹¹⁶ (but not apparently downregulated)¹¹⁷ by homologous tonicity elements in their 5' flanking sequence.¹¹⁶ These respond to a tonicity element binding protein that binds in response to hypertonic stress.^{116,117} By raising intracellular osmolality, sorbitol accumulation is presumed to downregulate these compatible osmolyte genes transcriptionally and/or to activate osmolyte efflux posttranslationally through the volume-sensitive osmolyte anion channel (VSOAC).¹¹⁸ Potentially, sorbitol-induced intracellular osmotic stress may contribute to depletion of reduced glutathione (GSH) and thereby exacerbate oxidative stress. Indeed, GSH depletion is aggravated in complication-prone tissues by therapeutic interventions such as sorbitol dehydrogenase inhibitors, which aggravate sorbitol accumulation,¹¹⁹ or by overexpression of the AR gene (Fig. 44-1).

AR-mediated oxidative stress may also promote MI and taurine depletion directly via downregulation of sodium-dependent MI transporter (SMIT) and the taurine transporter or indirectly through disruption of the (Na,K)-ATPase-generated Na⁺-gradient, which is required for the active uptake of MI and taurine.¹¹⁷ The ability of the antioxidant α -lipoic acid to correct nerve MI and

FIGURE 44-1. Potential mechanisms whereby activation of the aldose reductase pathway may exacerbate oxidative stress. Activation of the aldose reductase (AR) pathway consumes NADPH and provokes intracellular sorbitol accumulation, resulting in osmotic stress and the compensatory depletion of the organic osmolytes taurine and myoinositol and perhaps depletion of reduced glutathione (GSH). In turn, this will promote oxidative stress and alterations in signal transduction pathways. Sorbitol oxidation by sorbitol dehydrogenase (SDH) promotes the formation of NADH ("pseudo-hypoxia") and leads to the formation of fructose, which is a potent glycosylator. Increased oxidative stress results in disruption of vasoactive agents and reduced nerve blood flow, which compromises mitochondrial function, leading to nerve energy deficits and nerve conduction velocity (NCV) slowing.

taurine content^{87,120} implicates multiple interconnected pathways by which glucose flux through AR can result in osmolyte depletion. Therefore, in diabetes, AR activation may result in the depletion of intracellular osmolytes, rendering them rate-limiting for normal intracellular metabolism.^{80,81} In some cells, MI depletion is profound enough to limit the synthesis of phosphatidylinositol (PI) by cytidine-diphospho-diglyceride-inositol 3-phosphatidyltransferase (PI synthase),¹²¹ secondarily altering phosphoinositide (PPI) turnover and the generation of PI-derived second messengers such as diacylglycerols (DAGs) thought to critically regulate (Na,⁺K⁺)-ATPase.^{78,122} In concert, depletion of taurine, an important endogenous antioxidant,¹²³ calcium modulator,^{124,125} PKC antagonist,¹²⁵ and neurotransmitter,¹²⁶ may compound chronic cytotoxicity in diabetes by interaction with a complex matrix of biochemical mechanisms outlined below. However, as described below, ascribing nerve osmolyte depletion entirely to the osmotic stress resulting from exaggerated accumulation of intracellular sorbitol appears to be an oversimplification, as levels of nerve MI and taurine can be changed in diabetic and nondiabetic nerve independently of nerve sorbitol levels.

Depletion of nerve MI has been invoked as an important mediator of the effect of sorbitol pathway activation on NCV slowing in acute experimental diabetes,^{69,79,80} although this view has recently been challenged.^{109,127,128} Oral 1% MI supplementation, whether given in chow¹²⁹ or synthetic diet,^{79,80,130} corrects sciatic nerve MI depletion and reproduces the beneficial effects of ARI treatment on slowed NCV,^{102,103,131} reduced nerve blood flow,¹³¹ and the development of paranodal axonal swelling⁶⁹ in the STZ-D and spontaneously diabetic BB rat models of EDN. The oral dose of MI ap-

pears to be critical, since 3% MI supplementation is not efficacious and produces some slowing of MNCV in nondiabetic rats.¹⁰⁹ It may reflect reciprocal depletion of other compatible osmolytes such as taurine.¹⁰⁰ Feeding 1-fucose, a competitive inhibitor SMIT activity, to normal rats reproduces the nerve MI depletion and the impaired nerve electrophysiology and (Na,K)-ATPase activity found in diabetic rats; these are corrected by MI supplementation given simultaneously with 1-fucose.¹³² SMIT activity in diabetic nerve is competitively inhibited by glucose, but it remains diminished in diabetic nerve exposed to normal glucose *in vitro*,^{80,81} suggesting intrinsically impaired SMIT expression or function.

Depletion of intracellular MI has been thought to render it rate-limiting for the membrane PI synthesis and turnover⁸⁰ necessary for phospholipase C-mediated, G protein-associated signal transduction. This has been speculated to lead to diminished PI-derived DAG and impaired activation of PKC, which may link altered PI metabolism to defective (Na,K)-ATPase regulation in diabetic nerve. This assertion is based on the observations that (Na,K)-ATPase activity,^{80,133} arachidonyl-DAG,¹³⁴ and PKC activation are diminished in diabetic nerve and that dietary MI supplementation *in vivo*⁸⁰ or exogenous PKC agonists *in vitro*¹³⁵ correct impaired nerve (Na,K)-ATPase activity. In addition, MI depletion through its effects on signal transduction pathways and fatty acid metabolism may impair nitric oxide synthase (NOS) activity,^{133,136,137} and/or lipoxygenase/COX pathways,¹³⁸ resulting in widespread metabolic and vascular deficits through the disruption of nitric oxide (NO) and prostaglandin metabolism at the level of the sympathetic ganglia, peripheral neuron, or endoneurial vasculature.

Depletion of the β -amino acid taurine (2-aminoethanesulfonic acid)^{100,139,140} in complication-prone diabetic tissues including the peripheral nerve¹⁰⁰ has recently emerged as an important mediator of glucotoxicity. Taurine has antioxidant^{123,141} properties, and high taurine concentrations are found in tissues subject to oxidative stress, including rat lens,^{140,142} kidney,¹⁴³ heart,^{124,144} and nerve.¹⁰⁰ In the sciatic nerve, taurine levels are depressed in diabetic rats,^{100,145} and nerve taurine replacement ameliorates deficit of nerve blood flow, (Na,K)-ATPase activity, and NCV in EDN,¹⁴ suggesting an important modulatory role for taurine on nerve function.

Recently, an important role has emerged for taurine in the regulation of micro- and macrovascular function. Taurine has been demonstrated in the endothelial cells of rat cerebellar cortex capillaries as well as in the perivascular glia and neurons that innervate the vasculature, consistent with a role for taurine in the regulation of microvascular function within the CNS.¹⁴⁶ In human endothelial cells, taurine has also been shown to prevent apoptosis and maintain cell function after exposure to lipopolysaccharide, tumor necrosis factor- α , and calcium ionophore, supporting a role for taurine in antioxidative defense and regulation of intracellular calcium flux¹⁴⁷ in the endothelium. In STZ-D mice, a taurine-supplemented diet has been shown to normalize endothelium-dependent relaxation of aortic rings.¹⁴⁸ Immunohistochemical studies of the distribution of taurine in the peripheral nerve of diabetic rodents have localized taurine to the endothelium of the endoneurial vascular and Schwann cells,¹⁴⁵ consistent with its function in regulating endoneurial blood flow and (Na,K)-ATPase activity.

In addition to its antioxidant effects, taurine modulates intracellular Ca²⁺ flux^{124,125,144,149} and PKC activation.¹²⁵ Taurine lowers cytosolic Ca²⁺ by stimulating mitochondrial uptake,^{125,144} inhibiting PI turnover,¹²⁵ and decreasing internal Ca²⁺ flux,¹⁴⁴ thereby

inhibiting Ca^{2+} -dependent PKC activation.¹²⁵ Thus intracellular taurine depletion in diabetes may contribute to the glucose-induced activation of PKC, which has been invoked in the pathogenesis of diabetic complications^{150,151} including DPN.^{152,153} In addition, neuronal and glial taurine are thought to function as an osmoregulator, neuromodulator, or inhibitory neurotransmitter,^{126,154–156} as well as a neurotrophic agent.¹⁵⁷ Taurine may also modulate neuronal hyperexcitability by producing hyperpolarization or by inhibiting Ca^{2+} /calmodulin-dependent protein kinases, and its depletion may therefore play a role in the pathogenesis of painful neuropathy.¹⁰⁰

Polyol Pathway and Redox Potential

Glucose flux through AR and SDH oxidizes the NADPH/NADP and reduces the NADH/NAD redox couple, thereby disturbing the adenine nucleotide-linked reaction that functions near the redox equilibrium. Depletion of glutathione secondary to oxidation of the NADPH/NADP couple has been proposed to increase susceptibility to oxidative stress.¹⁰⁴ Alternatively, the reduction of NADH/NAD coupled to the oxidation of glucose-derived sorbitol to fructose favors lactate production and the diversion of glycolytic intermediates to the synthesis of phospholipid precursors such as α -glycerophosphate, phosphatidic acid, DAG, and cytidine-diphospho-diglyceride (CDP-DG). This flux may also interfere with β -oxidation of long-chain fatty acids, resulting in a metabolic “pseudohypoxia.”

Both AR-mediated NADPH oxidation and SDH-mediated NAD reduction have been implicated in diabetes-induced changes in nicotinamide adenine nucleotide homeostasis (increase in free cytosolic $\text{NADP}^+:\text{NADPH}$ and decrease in free cytosolic $\text{NAD}^+:\text{NADH}$ ratios) as well as the antioxidant and metabolic deficits contributing to diabetic neuropathy, retinopathy, and cataract formation.^{97,158–160} In particular, it has been suggested that a deficiency of NADPH, a cofactor shared by AR, glutathione reductase, and NOS, is responsible for diabetes-induced depletion of GSH and total glutathione, and thus enhanced oxidative stress, in the lens and peripheral nerve,^{104,133,158} and decreased endoneurial nutritive blood flow.¹⁵⁸ There are a number of findings, however, that are difficult to reconcile with these putative redox cycling mechanisms: (1) the absence of a reciprocal increase of oxidized glutathione (GSSG) levels in concert with the diabetes-induced decrease in GSH levels in the peripheral nerve¹⁶¹; (2) a decrease in free cytosolic $\text{NADP}^+:\text{NADPH}$ ratios in the nerve¹⁶² of acutely diabetic rodents; and (3) exacerbated depletion of nonenzymatic antioxidants (GSH and ascorbate) and increased lipid peroxidation in diabetic peripheral nerve by SDH inhibition.¹⁶³ None of these three factors are consistent with the possibility that increased redox cycling mechanisms contribute to diabetic complications.

It has been proposed that SDH-mediated NAD-redox imbalances (so-called pseudohypoxia) constitute the principal mechanism responsible for polyol pathway-mediated diabetic complications.⁹⁷ This has been explored in rodent models using sorbitol dehydrogenase inhibitors (SDIs),^{164,165} as well as SDH-deficient and SDH-knockout mouse models.^{160,166} SDH was found to accelerate, rather than retard, the development of autonomic dysfunction.¹⁶⁶ In the peripheral nervous system there have been conflicting results: Some laboratories have found beneficial effects of SDIs on nerve electrophysiologic deficits using a prevention paradigm in diabetic rats,¹⁶⁷ whereas others have failed to find any beneficial effect on neurovascular or functional deficits using an interventional approach.¹⁶⁴ Moreover, the relationship of polyol accumulation

and nerve dysfunction has also been explored in SDH-deficient mutant mice (C57BL/LiA), which have exaggerated sorbitol accumulation but fructose depletion in the peripheral nerve. Diabetic SDH-deficient mice showed MNCV slowing similar to that in normal diabetic mice, thereby suggesting that increased flux through SDH is not responsible for MNCV slowing in experimental diabetes.¹⁶⁵

Recent reports have reinforced the view that increased flux through SDH cannot account for changes in the dynamic system of nicotinamide nucleotides in complication-prone diabetic tissues. SDI treatment that resulted in >90% inhibition of increased flux through SDH in the nerve failed to ameliorate free cytosolic $\text{NAD}^+:\text{NADH}$ ratios and actually exacerbated tissue oxidative stress and energy deficiency (manifested by accumulation of lipid aldehydes and further reductions in GSH, PCr, and PCr:Cr ratio in the peripheral nerve of SDI-treated diabetic rats).^{163,168} Potentially, diabetes-induced NAD-redox imbalances could promote oxidative stress by resulting in the accumulation of triose phosphates (DHAP and GP), with their subsequent auto-oxidation and formation of methylglyoxal,¹⁶⁹ which generates free radicals and impairs antioxidant defense.¹⁷⁰ Exacerbation of tissue oxidative injury in spite of improvement in $\text{NAD}^+:\text{NADH}$ ratios coupled with SDI treatment¹⁶⁸ suggests that adverse effects (potentially mediated in part by osmotic disturbances such as taurine depletion) predominate over putative beneficial (NAD-redox) effects of SDH inhibition on oxidative stress.

The ability of other metabolic manipulations to improve nerve conduction or other aspects of the neuropathy associated with diabetes in the rat implies the existence of other contributory factors, some of which may or may not be related to the sorbitol pathway. In particular, various compounds that promote vasodilation improve nerve electrophysiology in experimental diabetes, as do compounds with either neurotransmitter or neurotrophic action. Furthermore, recent observations are consistent with the hypothesis that reductions in cyclic AMP in rat nerve may contribute to impaired (Na,K)-ATPase activity.

Signal Transduction, Nerve Osmolytes, and Nerve Conduction

Glucose-induced alterations in signal transduction pathways are thought to play a critical role in the development of DPN. However, heterogeneous and complex cell-specific relationships between ambient glucose and intracellular signaling have been reported. Hyperglycemia may alter PI signal transduction by two separate mass-action mechanisms with antiparallel effects. In neuronal tissue, glucose-induced, AR-catalyzed sorbitol accumulation and reciprocal MI depletion may diminish PI synthesis and turnover and the subsequent release of PI-derived arachidonyl-DAGs, resulting in decreased PKC activity. Indeed, a reduction in arachidonyl-containing DAGs and PKC activity has been demonstrated in diabetic rat sciatic nerve.^{134,135} Inhibition of PKC can also prevent the decrease of sciatic nerve (Na,K)-ATPase but is not able to prevent the decrease in glutathione peroxidase activity that has been reported in diabetic mice.¹⁷¹

However, in vascular tissues, including potentially the neurovasculature, the predominant effect of elevated glucose has been reported to be PKC activation.^{150,172,173} The importance of glucose-induced activation of PKC in some tissues prone to diabetic complications has received some support by the recent demonstration that a specific PKC $\beta 1$ inhibitor could correct diabetes-induced

retinal and renal dysfunction in the STZ-D rat.¹⁵¹ Recently, two studies have reported the effects of PKC inhibition on metabolic, neurovascular, and functional deficits in diabetic rats. In STZ-D rats, inhibitors of PKC (WAY151 003 and chelerythrine) dose-dependently corrected deficits of nerve perfusion, (Na,K)-ATPase activity, nerve MI content,¹⁵² and NCV without affecting nerve glutathione content.¹⁵³ At high dose, the inhibitors dissociated nerve blood flow (corrected) from nerve conduction (uncorrected) deficits. The beneficial effects were prevented by NOS inhibitor cotreatment.¹⁵³

Since the effects of activation or inhibition of PKC can be expected to have divergent tissue-specific regulatory effects (e.g., on [Na,K]-ATPase activity and NOS activity), tissue nonselective pharmacologic blockade (or activation) of PKC isoforms could be expected to ameliorate the effects of hyperglycemia in some tissues, but they may aggravate glucotoxicity in others.

The concept that depletion of nerve osmolytes in diabetic tissues is simply a result of osmotic compensation for glucose-induced sorbitol accumulation appears to be an oversimplification. This view is supported by the following recently reported data: Nerve acetyl-L-carnitine replacement in STZ-D rats corrects nerve MI levels independently of polyol pathway activity¹⁷⁴; the chain-breaking antioxidant α -lipoic acid prevents nerve taurine and MI depletion, despite exacerbating nerve sorbitol accumulation; and, in nondiabetic rats,^{83,87} nonselective COX inhibition with flurbiprofen can reproduce diabetes-induced depletion of nerve taurine and MI. These data suggest that nonosmotic metabolic factors may play a critical role in the regulation of nerve organic osmolyte levels. Intracellular levels of taurine and MI are regulated by transmembrane transport mediated by their Na-dependent cotransporters (regulating cellular uptake) and VSOAC (regulating cellular efflux).¹⁰⁴ These transport mechanisms are critically regulated by signal transduction pathways, with PKC activation appearing to have parallel inhibitory effects on transmembrane transport of MI and taurine and stimulation of efflux.¹⁰⁴ Thus the beneficial effects of PKC inhibition on nerve MI content could be explained by direct effects on nerve MI flux.

Recently, a consensus has begun to emerge suggesting that the effects of diabetes on protein kinase signal transduction in the nerve are complex and tissue-specific: PKC activation in the vasculature may contribute to nerve blood flow deficits, whereas a reduction of PKC activity in neuronal tissues may alter nerve metabolism at this site.

(Na,K)-ATPase Activity

The absence of prominent demyelination or nerve fiber degeneration, in association with the nerve conduction slowing in acutely diabetic rats,^{74,175} suggested a biochemical or biophysical mechanism, which might also account for the associated paranodal swelling and increased intra-axonal sodium content in diabetic rat nerve.¹⁷⁶ The (Na,K)-ATPase emerged as a possible common denominator for altered energy metabolism, nerve conduction slowing, and paranodal swelling in acute experimental diabetes based on direct measurement of reduced nerve (Na,K)-ATPase activity in diabetic rodents, its correction by multiple metabolic interventions that ameliorate electrophysiologic deficits,¹⁰⁴ and voltage clamp studies documenting a corresponding reduction in the resting axolemmal membrane potential and a four- to fivefold increase in intra-axonal [Na⁺].¹⁷⁶ Recent studies have demonstrated that pharmacologic manipulation of nondiabetic rats with agents that decreased nerve (Na,K)-ATPase

activity also reproduces diabetic NCV slowing.¹³³ Flux through the COX pathway appears to regulate nerve ATPase activity tonically.¹⁷⁷ In EDN, PGE₁ analogs¹¹⁰ and cilostazol (a phosphodiesterase inhibitor) correct the reduced cAMP levels and prevent the decrease in ATPase activity in STZ-D rats. The potency of nonselective COX-1 and -2 inhibition to disrupt nerve ATPase activity contrasts with its lack of effect on ATPase activity in vascular tissue.¹³⁶

The importance of impaired ATPase activity in mediating the early decrease in motor NCV in EDN is debated, as ouabain-sensitive (Na,K)-ATPase activity is not detectably decreased before 4 weeks of diabetes, and (Na,K)-ATPase activity can be ameliorated without ameliorating MNCV slowing.¹⁷⁴ This discordance may be explained by differences in fiber type and/or differences in an isoform of the ATPase (or phosphorylation of its regulatory domain), which principally contributes to these measurements. For example, MNCV is determined by rapidly conducting large myelinated fibers, in which significant concentrations of ATPase enzyme may be limited to the paranodal Schwann cell processes and the nodal axolemma.¹⁷⁸ In these fibers (and their Schwann cells), the predominant isoform may be the $\alpha 1$, which is highly ouabain-resistant in rodents.^{179–181} In contrast, much of the measured composite ouabain-inhibitable (Na,K)-ATPase activity in whole sciatic nerve may reside in the ouabain-sensitive $\alpha 2$ and $\alpha 3$ isoforms^{179,180} of the unmyelinated nerve fibers,¹⁸¹ which contribute little to the measured MNCV. Alternatively, composite ATPase correction may be necessary but not sufficient alone to correct MNCV slowing.

The (Na,K)-ATPase is a heterodimer comprised of an α subunit (112 kd), which contains the catalytic subunit and the ATP- and ouabain-binding site¹⁸² and is the substrate for protein kinases, and a β subunit (35 kd), which may be important for membrane binding. Three different isoforms of the α subunit have been identified ($\alpha 1$, $\alpha 2$, $\alpha 3$), with $\alpha 1$ predominating in peripheral nerve and the Schwann cell.¹⁸⁰ In STZ-D, a marked and rapid insulin-sensitive reduction in the $\alpha 1$ subunit has been demonstrated by Western analysis after 3 weeks of diabetes, the reductions of the other subunits being delayed.¹⁷⁹ More recently, a diabetes-induced decrease in the $\alpha 2$ subunit and an increase in the $\beta 2$ subunit of the (Na,K)-ATPase has been reported in the Schwann cells (both) and node of Ranvier ($\alpha 2$ only) of diabetic rats.¹⁸³ Fish oil selectively corrected the change in the $\alpha 2$ subunit.¹⁸³ In general, the effects of experimental diabetes on differential regulation of the (Na,K)-ATPase subunits remain poorly understood.

PKC activation may itself have bidirectional, tissue- and species-specific effects on ATPase activity. Exogenous PKC agonists correct impaired nerve ouabain-sensitive energy metabolism and ATPase activity *in vitro*.¹⁸⁴ Moreover, PKC activation is without effect on the phosphorylation state of the α subunit in nerves from ND rats,¹⁸⁰ whereas in the STZ-D rat, increased α subunit ³²P labeling has been observed with PKC activation. However, PKC $\beta 1$ inhibition has been reported to dose-dependently prevent decreased (Na,K)-ATPase activity in STZ-D rats, and PKC activation has been associated with diminished (Na,K)-ATPase activity in peripheral nerve in the chronically diabetic mouse.¹⁸⁵ Thus, in EDN, the relationships of PKC to (Na,K)-ATPase activity are complex and poorly understood and may be both model- and time-dependent. Potentially chronic stimulation of PKC in EDN could result in compensatory up- or downregulation of its action. Finally, in T1DM subjects, patients with an ATP1 A1 variant of the genes encoding for (Na,K)-ATPase (when detected by Bgl II restriction fragment length polymorphism) were found to have diabetic polyneuropathy more frequently than those without,¹⁸⁶ providing

some support in humans for alterations in (Na,K)-ATPase activity in the development of DPN.

The Role of Ischemia and Other Alterations in the Endoneurial Microenvironment in the Pathogenesis of Diabetic Neuropathy

The contributory role of nerve ischemia to diabetic neuropathy has been an area of active investigation, with many modern experts supporting a hypothesis originally generated by Fagerberg¹⁸⁷ over 35 years ago. Originally based on extensive autopsy findings of thickened, para-aminosalicylic acid-positive deposits and luminal occlusion in endoneurial microvessels, the hypothesis in its current form is based on modern morphometric analysis of autopsy or biopsy material,^{188,189} sural nerve biopsies,^{22,143} and studies in diabetic animals.^{80,81} Currently, new efforts have been made to reconcile or merge these two hypotheses, which are not necessarily mutually exclusive.^{80,190}

Hemodynamic and oximetric and recent biochemical measurements in diabetic rodents suggest reduced endoneurial blood flow and hypoxia in chronically diabetic rats,^{127,191} which may occur as early as 1 week after the induction of diabetes.¹²⁷ Decreased nerve blood flow has been reported for both exposed^{153,159,164,192-196} and unexposed¹⁹⁷ nerve. In EDN, endoneurial nutritive flow has been reported to be reduced by 45% and nonnutritive flow by 48%.¹⁰⁹ A wide variety of vasoactive agents partially or completely correct NCV slowing in diabetic rats, including those with direct vasodilatory actions such as the α -adrenergic receptor inhibitor prazosin,¹²⁸ angiotensin-converting enzyme (ACE) inhibitors,¹⁹⁸ prostaglandin analogs,¹¹⁰ NO donors,¹⁹⁹ and potassium channel openers,²⁰⁰ and those with a more indirect vasodilatory action (i.e., ARIs,^{80,190} anti-

oxidants,²⁰¹⁻²⁰³ metal chelators,²⁰⁴ acetyl L-carnitine,^{174,205} PKC inhibitors,^{152,153} and evening primrose oil [EPO]²⁰⁶). Diabetic nerves may be more susceptible to ischemic injury due to imbalance of vasoactive agents.²⁰⁷ In EDN, 2 weeks of treatment with the β 2-AR agonist salbutamol or the α 1-AR antagonist doxazosin has recently been shown to partially reverse neurovascular dysfunction and NCV slowing in 8-week STZ-D rats, effects that appeared to be dependent on NO, implicating a role for vasa nervorum α 1- and β 2-AR in the regulation of nerve blood flow.²⁰⁸

ARI treatment prevents or corrects NCV slowing,^{80,190} corrects decreased endoneurial blood flow,^{109,110} and also impairs endothelium-dependent aortic relaxation (thought to be NO-mediated) in chronically streptozocin-diabetic rats.²⁰⁹ Indeed, several studies now suggest that microvascular dysregulation in diabetes may primarily involve the endothelial-dependent NO-mediated component.^{210,211} Finally, NOS inhibition reproduces the glucose-induced decrease in (Na,K)-ATPase activity in isolated rabbit aortic rings *in vitro*.¹³⁶

These observations together provide the framework for a metabolic-vascular pathogenetic matrix for experimental diabetic neuropathy involving AR, NO, and (Na,K)-ATPase (Fig. 44-2). A role for hyperviscosity as a cause of endoneurial hypoxia has also been proposed and is supported by findings of increased fibrinogen or globulin levels²¹² and decreased red cell deformability and/or leukocytosis and leukocyte activation in diabetes, but this area remains extremely controversial.²¹²

However, the concept of reduced nerve blood flow and endoneurial hypoxia has not received universal acceptance, since other reports have suggested that blood flow is unchanged²¹³ or increased²¹⁴ and that nerve conduction deficits reflect principally metabolic²¹⁵ or other²¹⁶ perturbations. A recent report in 12-week

STZ-D rats identified an increased number of microvessels supplying the peripheral nerve trunk; it was suggested that these reflected a neovascularity.²⁰⁷ Recently, evidence in support of endoneurial hypoxia was sought by the determination of biochemical adenine nucleotide-linked redox couples in the nerve. Free NAD⁺:NADH ratios in nerve mitochondrial cristae and matrix and cytosol were decreased by 77%, 32%, and 27% after 6 weeks of experimental diabetes in the rat.²¹⁷ The diabetes-induced reductions of free NAD⁺:NADH ratios in the mitochondrial matrix and cytosol were prevented by treatment with the vasodilator prazosin.²¹⁷

Clinical evidence in support of nerve hypoxia in the development of DPN has been the finding of a reduction of endoneurial oxygen in the sural nerves of diabetic patients with far advanced polyneuropathy²¹⁸ and the development of some abnormalities of neural conduction in nondiabetic hypoxic patients with chronic obstructive airway disease.²¹⁹ More recently, microlight-guided spectrophotometry has been used to measure intravascular oxygen saturation and blood flow in the sural nerve of diabetic subjects with and without diabetic neuropathy. These studies identified a reduction of nerve oxygenation and impaired nerve blood flow in subjects with diabetic neuropathy.²²⁰ Finally, the ACE inhibitortrandolapril has recently been shown to improve peripheral nerve electrophysiology after 12 months in diabetic subjects with mild neuropathy.²²¹

Thus, although hypoxia may play a role in the development of diabetic neuropathy, it probably is not the sole factor. Recently, the importance of the anatomic arrangement of the nerve vasculature has been highlighted in mediating both the diabetes-induced deficits of nerve blood flow and the effects of vasoactive therapeutic interventions. The nerve vascular supply comprises an intrinsic system consisting of microvessels, which are situated longitudinally within the fascicular endoneurium, and an extrinsic system composed of the larger nutritive arteries, arterioles, venules, and epineural vessels. The nerve has only a very limited capacity to autoregulate its vascular supply²²²; perhaps only the epineural and perineural vessels are capable of autoregulation. This means that alterations in system pressure lead to passive fluctuations in perfusion in the nerve,²²² and so assessments of nerve perfusion are best expressed as a "vascular conductance" that corrects for mean blood pressure.¹⁹⁸ Extensive anastomoses (both arteriovenous [AV] and arterioarterial) are formed between the two systems by the epi- and perineural vessels, which, together with the low metabolic requirements of the nerve, confer a resistance to ischemic insults.²²³ Extensive perineural AV anastomoses have recently been demonstrated in neuropathic diabetic subjects and have led to speculation regarding the role of a steal phenomenon, in which the nutritive endoneurial capillary flow is impaired by the high shunt flow.²²⁴ Conversely, whether this putatively increased shunt flow is a result of chronic endoneurial ischemia/sclerosis is unknown. Many successful therapeutic interventions have been shown to regulate endoneurial nutritive and/or AV shunt flow differentially.

Oxidative Stress and EDN

Oxidative stress has recently emerged as a critical factor in the development of chronic diabetic complications^{202,225–227} and a leading candidate in the development of nerve blood flow and nerve conduction deficits.^{83,87,159,161} Malonyldialdehyde, a degradation product of lipid hydroperoxide, is increased in experimental²²⁸ and human diabetes,²²⁹ and levels of circulating antioxidants including ascorbic acid, platelet vitamin E, and taurine are decreased in

human^{230,231} and experimental diabetes.^{228,232} In recently diagnosed T1DM patients, plasma levels of conjugated lipid dienes have been reported to be elevated, whereas in longer duration diabetes, levels of thiobarbituric acid reactive substances (TBAR) and lipid hydroperoxide were increased additionally.²³³ These alterations have been ascribed to increased antioxidant consumption from increased oxidative stress or to transition metal-catalyzed glucose "auto-oxidation."^{225,234} Increased oxygen free radical activity in diabetes is reversed by insulin²³⁵ or ARIIs²³⁶ and has been ascribed to glucose-protein interactions,²³⁷ to auto-oxidation of glucose,^{225,226,234} and to glucose-induced activation of the AGE pathway.^{236,238}

In the endoneurial vasculature, oxidative stress has been implicated in the development of endoneurial ischemic hypoxia, in impaired oxidative metabolism, and nerve energy deficits. Support for this construct has been provided by the recent identification of lipoic acid-sensitive GSH and GSH+GSSG depletion^{83,87} and decreased mitochondrial and cytoplasmic NAD⁺:NADH ratios,^{87,2} together with vasodilator-responsive reductions of PCr:Cr and ATP:ADP ratios²¹⁷ in the sciatic nerve of 6-week STZ-D rats. These data are consistent with impaired mitochondrial oxidative phosphorylation, secondary to oxidative stress and ischemic hypoxia.

In EDN, the reduction in nerve blood flow and resultant hypoxia do not appear to be a principal contributor to oxidative stress since amelioration of nerve blood flow deficits by prazosin does not alter indices of oxidative stress in the sciatic nerve in STZ-D rats.²¹⁷ In diabetic rodents, impairment of the blood-nerve barrier,²³⁹ increased nerve conjugated dienes,^{240,241} and reduced levels of nerve superoxide dismutase (SOD),²⁴¹ glutathione peroxidase,²⁴¹ glutathione,^{201,242} norepinephrine,²⁴³ and taurine,¹⁰⁰ as well as impaired neurotrophism,^{129,244} provide support for the presence of increased oxidative stress. However, the mechanisms leading to paradoxical downregulation of antioxidant defense enzymes in the nerve of diabetic rodents are complex and poorly understood. In STZ-D rats, gene expression of glutathione peroxidase, catalase, cuprozinic superoxide dismutase, and manganese SOD was not decreased in the L4,5 dorsal root ganglion (DRG) and superior cervical ganglion after 3 or 12 months of diabetes.²⁴⁵ Catalase mRNA was increased, however, after 12 months. Glutathione peroxidase activity is unaffected in the sciatic nerve of STZ-D rats. These observations suggest that glucose-induced posttranslational modifications may play an important role in altered antioxidant defense enzyme activity.

In EDN, increased oxidative stress may decrease nerve blood flow by disruption of signal transduction pathways in the vascular endothelium¹⁵⁰ or in the sympathetic ganglia.²⁴⁶ Oxidative stress may lead to apoptosis in the vascular endothelium,^{247,248} thereby impairing the synthesis or action of local vasodilatory agents. Oxidative stress can perturb prostanoic acid synthesis (see below)²²⁸ and NO synthesis²⁴⁹ in diabetes, and impaired endothelium-dependent relaxation in hyperglycemic rabbits can be corrected by probucol.²⁵⁰ Essential fatty acid metabolism is disrupted by ROS, and therapeutic synergism has been reported between γ -linolenic acid and antioxidants.¹⁵⁹ Attenuation of oxidative stress by the administration of antioxidants can correct nerve blood flow and functional deficits *in vivo*.^{86,87,159,161}

The endothelium-derived relaxing factor NO mediates vasodilation, macrophage cytotoxicity, and neurotransmission²⁵¹ and is highly susceptible to oxidative stress in diabetes.^{251,252} NOS, the enzyme catalyzing the conversion of L-arginine to citrulline and NO at the expense of NADPH, is critically situated in endothelial

cells, vascular smooth muscle cells, and sympathetic ganglia. NOS is constitutively expressed in endothelial (eNOS) and neuronal (nNOS) cells, and activity is critically dependent on posttranslational modification by calcium/calmodulin-dependent protein kinases and PKC.²⁵¹ Impaired synthesis of NO has been linked to polyol pathway activation through an NADPH-mediated mechanism (via the redox hypothesis), as well as alterations in protein kinase activation and calcium levels (via the osmotic hypothesis). Metabolic competition for NADPH by AR and NOS could precipitate NO depletion^{133,209} via both decreasing NO synthesis and increasing levels of superoxide radicals, since NADPH is required for the production of GSH.

Additionally, increased formation of advanced glycosylation end products by glucose and fructose may also quench NO. It has been proposed that heavily glycosylated proteins in the arterial wall have increased affinity for transition metals, leading to accelerated destruction of NO and persistent vasoconstriction. The beneficial effects of many therapeutic agents on nerve blood flow and MNCV slowing are thought to be mediated by NO, as well as antioxidants, ARIs, EPO, and acetyl L-carnitine.^{80,190}

Oxidative stress may also exacerbate nerve metabolic defects in diabetes, by disrupting nerve (Na,K)-ATPase activity,²⁵³ which may lead to disruption of unmyelinated nerve fiber function, and by impairing the function of the Na⁺-dependent cotransporters for MI and taurine.^{80,190} Support for a role of oxidative stress in EDN is provided by the ability of antioxidants and pro-oxidants to prevent or provoke, respectively, functional nerve deficits. Lipid-soluble antioxidants^{201,202,227} (such as probucol, the free radical scavenger and glutathione precursor N-acetylcysteine,²⁰³ glutathione itself,²⁰¹ the chain-breaking antioxidant lipoic acid,^{86,87,159,161} and the natural antioxidant vitamins C, E, and β -carotene¹⁹²) prevent vascular defects and NCV slowing in diabetic animals. The advanced glycosylation end product (AGE) inhibitor aminoguanidine prevents motor and sensory NCV deficits^{196,254,255} in diabetic rats and also prevents the reduction in nerve blood flow.²⁵⁴ Conversely, aggravation of oxidative stress with primaquine in nondiabetic rats partially reproduces diabetic nerve dysfunction.²²⁷ Impaired peripheral nerve function has been reported to improve in T2DM subjects treated for 6 months with 900 mg/day of vitamin E.²⁵⁶

Amelioration of oxidative stress may emerge as the principal mechanism of action of the ARIs.¹⁰⁵ Advanced glycation is exacerbated by high polyol pathway flux, since fructose is a more potent glycosylating agent than glucose, as are the intermediates and products of the hexose monophosphate shunt that generates NADPH for AR.²⁵⁷ High flux through the polyol pathway may consume NADPH, required for the reduction of glutathione, which is involved in glutathione peroxidase-catalyzed removal of peroxide formed by the scavenging action of SOD on oxygen free radicals.²²⁷

A number of observations suggest that the beneficial effects of ARIs in diabetes may involve decreasing oxidative stress by a mechanism that may involve direct antioxidant effects as oxygen free radical scavengers or effects on cellular redox, glutathione, or taurine concentrations.²³⁷ The ARIs sorbinil and rutin²⁵⁸ inhibited collagen-linked fluorescence and increased vascular permeability in diabetic animals. In diabetic patients, the ARI tolrestat decreases plasma oxygen free radical levels.²³⁸ ARIs may also work partly by binding free copper ions (and thus blocking copper-catalyzed ascorbate oxidation²³⁷) and by preventing depletion of the endogenous antioxidant taurine.

Therefore, accumulating evidence suggests a central role for increased oxidative stress in the pathogenesis of EDN. The avail-

ability of a plethora of naturally occurring and synthetic antioxidants should also accelerate the instigation of clinical trials to evaluate their efficacy in humans.

Nonenzymatic Glycation

Nonenzymatic protein glycation is a widespread biochemical phenomenon by which glucose and its metabolites may alter cellular composition, function, or both in diabetes. Nonenzymatic formation of Schiff base residues between glucose and the amine groups of proteins (with subsequent Amadori rearrangement) yields glycosylated proteins including hemoglobin.^{225,226,234,257} More complex heterocyclic carbohydrate-protein adducts (AGEs) in diabetes lead to protein-protein cross-links and liberation of highly reactive free radicals that structurally alter extracellular matrix and promote cytotoxicity, NO quenching, and macrophage activation via the AGE receptor,²⁵⁹ a cascade central to current thinking regarding the pathogenesis of diabetic complications. Protein glycation could involve the vascular supply, the extracellular matrix, or the cellular constituents of peripheral nerve. Protein glycation could produce vascular damage by generation of free oxygen radicals or through the formation of advanced glycation end products that in turn stimulate cytokine and growth factor release from activated macrophages, resulting in smooth muscle cell proliferation, atherogenesis, and vascular occlusion. Nonenzymatic glycation of extracellular matrix proteins could interfere with their neurotrophic or neurosupportive effects. Involvement in the pathogenesis of DPN is suggested by evidence that glucose-protein adducts on laminin reduce its support of neurite outgrowth *in vitro*²⁶⁰ and that aminoguanidine (which among other actions impedes the formation of complex sugar-protein adducts) ameliorates some of the characteristic defects of EDN.^{254,255}

Recent studies, however, suggest that glucose has a particularly low glycosylation potential among sugars, especially compared with fructose and its metabolites. In particular, a novel metabolic pathway that enzymatically phosphorylates fructose (and possibly sorbitol) leading to fructose-3-phosphate (and possibly sorbitol-3-phosphate), which subsequently degrades to 3-deoxyglucosone (3DG), a particularly potent glycosylating agent.²⁶¹ Thus, AR pathway flux, which converts glucose (with its low glycosylating potential) into fructose and sorbitol, their phosphorylation by a 3-phosphokinase,²⁶¹ and subsequent degradation to 3DG would radically accelerate the formation of the complex heterocyclic carbohydrate-protein adducts known as AGE.

Oxidative Stress, Programmed Cell Death, and Diabetic Neuropathy

Generation of ROS has been implicated in the signaling pathway leading to programmed cell death (PCD).²⁶² PCD leads to the deletion of cells during development or pathogenesis through a gene- and protein-regulated process. The morphologic endpoint of PCD, referred to as apoptosis, results from the degradation of genomic DNA, plasma membrane alterations, and the activation of caspases. PCD has been identified as the mechanism of cell death in a number of human neurodegenerative disorders²⁶³ and has been implicated in the development of chronic diabetic complications. For example, PCD of vascular endothelium has been demonstrated *in vivo* in the aorta of diabetic rats.²⁶⁴ In addition, ROS-mediated PCD is induced following glucose exposure in cultured human endothelial cells.^{265,266}

Diabetic nephropathy is characterized by DNA fragmentation accompanied by evidence of oxidative stress²⁶⁷ and also by the downregulation of Bcl-2.²⁶⁸ The impaired wound healing observed in diabetes is associated with increased DNA fragmentation²⁶⁹ and dysregulated expression of Bcl-2 and p53²⁷⁰ in diabetic mice. Retinopathy in human diabetes has been linked to PCD in pericytes of the inner retina through increased expression of Bax and plasma membrane alterations²⁷¹ and increased caspase 1 expression.²⁷² Glucose-induced PCD in pericytes is associated with decreased SOD²⁷² and GSH,²⁷² suggesting that pericyte PCD involves oxidative stress. Neurons in the retina also display PCD-associated DNA fragmentation during experimental and human diabetes.²⁷³ In addition to neurons of the retina, sensory neurons also are susceptible to the induction of PCD during hyperglycemia.^{82,274,275} Sensory neurons of diabetic, but not normal, rats undergo PCD following axonal injury through an oxidative stress mechanism.²⁷⁶ Finally, sera from diabetic subjects has been demonstrated to induce apoptosis in cultured neuroblastoma cells.^{273,277,278}

Alterations of gene expression, such as increasing p53 or Bax, or decreasing Bcl-2, may be initiating steps in PCD. The relative abundance of the Bcl family of proteins including Bcl-2, Bax and Bcl-x_L,²⁷⁹ which primarily are located in the inner mitochondrial membrane, appears to critically regulate the threshold for activation of the apoptotic cascade. Bcl-2 is antiapoptotic and inhibits the opening of a large mitochondrial conductance channel.²⁸⁰ The opening of this channel results in mitochondrial depolarization, expansion of the intermembranous space, outer membrane rupture, and the release into the cytosol²⁸⁰ of enzymes (such as cytochrome C and/or apoptotic-protease activating factor-1 (Apaf-1)) that activate the caspase cascade. Apoptosis is increased by a shift in the balance toward Bax homodimers, whereas the formation of Bcl-2/Bax or Bcl-x_L/Bax heterodimers inhibit PCD.²⁸¹

Recent reports have suggested that PCD contributes to sensory and autonomic neuron dysfunction in STZ-D rats,^{282,283} as well as in acutely hyperglycemic ND rats.²⁸² In diabetic rats, apoptosis of DRG neurons has been reported to be induced by axonal injury; such injury could be reversed by PGE₁ treatment, which promotes axonal regeneration.²⁷⁶ Increased intracellular calcium has been invoked as a key mediator of apoptosis in DRGs from both diabetic rodents. Indeed, in dorsal horn neurons from diabetic rats, the activity of the N- and L- but not T-type voltage-gated channels has been reported to be increased.²⁸⁴

Recently, a pivotal role for the mitochondria has emerged in controlling PCD.²⁸⁵ In STZ-D, for example, morphologic changes of PCD, such as Schwann cell degeneration, myelin ballooning, reduction of neuronal perikaryal volume, and shrinkage of the axoplasm are associated with markers of mitochondrial dysfunction, such as mitochondrial ballooning and impairment of basal mitochondrial membrane potential.^{282,283} Elevated (more positive) mitochondrial membrane potential in diabetic STZ-D rat DRG neurons has been reported as early as 4 weeks after the onset of diabetes.²⁸³ In STZ-D rat DRG neurons, decreased Bcl-2 and translocation of mitochondrial cytochrome C to the cytosol has been pathogenetically associated with activation of the apoptosis cascade, resulting in cleavage of the death effector caspase 3.^{282,283} The mechanism underlying the reduction of Bcl-2 abundance is unknown. Unlike Bcl-2, no differences in the abundance of the antiapoptotic protein Bcl-x_L or Bax protein²⁸³ (which promotes hyperglycemia-induced apoptosis in mouse blastocysts²⁸⁶) were identified in neurons from diabetic rats.

Many PCD promoters, including toxic agents and radiation, operate through the generation of ROS. The significance of during the induction of PCD has been demonstrated by the use of antioxidants to inhibit the response. This process, then, becomes significant in diabetes, since hyperglycemia can increase the generation of ROS through several mechanisms, as described above. Since mitochondrial dysfunction in STZ-D rats can be corrected by antioxidant therapy,⁸⁷ since ROS-induced PCD may share similar cell death pathways with neurotrophin withdrawal,²⁸⁷ and since nerve growth factor (NGF) can block mitochondrial oxidative damage,^{263,288,289} it is tempting to speculate that diabetes-induced increased oxidative stress is the inciting event that triggers neuronal PCD. The recent discovery that the antiapoptotic Bcl-2 gene product has antioxidant properties lends further support to the importance of oxidative events in PCD.^{290,291} Therapeutic strategies as antioxidants and/or caspase inhibitors may therefore have considerable potential for the prevention or treatment of DPN.

The COX Pathway and Diabetic Neuropathy

Alterations in COX activity and subsequent perturbations in prostanoic acid metabolism have also been invoked in the pathogenesis of experimental DPN at a neurovascular level. However, in experimental DPN, the effects of COX inhibition on neurovascular functional deficits have been inconsistent. Initial reports suggest that nonselective COX inhibition could ameliorate certain specific deficits of nerve function in experimental diabetes^{292,293}; however, other investigators could not confirm any beneficial effects.²⁹⁴ Nonselective inhibition of the COX pathway with flurbiprofen in nondiabetic (ND) rats has recently been reported to replicate, in STZ-D rats, many of the biochemical and physiologic abnormalities of experimental DPN. In contrast, selective COX-1 inhibition did not affect nerve blood flow or nerve conduction in ND rats and prevented MNCV slowing and nerve blood flow deficits in STZ-D rats. A possible explanation for the apparent consistency in the effects of different COX inhibitors on both nerve conduction and nerve blood flow deficits in STZ-D rats is unknown, but it may reflect differences in the relative degree of inhibition of the two COX pathways (see below).

Two COX isoforms have been identified.²⁹⁶ COX-1 is constitutively expressed in a variety of cells and tissues including the vascular endothelium,²⁹⁷ whereas inducible COX-2 is associated with proinflammatory stimuli, such as cytokines, growth factors, tumor promoters,²⁹⁸ and oxidative stress.²⁹⁹ A potential link between oxidative stress and alterations in PG synthesis appears to be the transcription factor NF- κ B, which is activated by ROS.³⁰⁰ Additionally, hypoxia has also been shown to induce COX-2 expression in cultured endothelial cells³⁰¹ and rodent brains,³⁰² suggesting that the effects of oxidative stress on the COX pathway could be mediated by several different pathways.

The interrelationships of COX and ROS are, however, complex, since ROS-induced activation of COX-2 can in itself increase ROS production, during PGG₂ to PGH₂ conversion, which generates hydrogen peroxide.²⁹⁷ However, since COX-2 activation can have a protective function on a number of physiologic processes,³⁰ it is reasonable to conclude that the regulation and consequences of COX-2 expression are highly dependent on both the site of expression and the underlying pathophysiologic condition. Although there is some evidence of COX-2 involvement in brain ischemia and neurodegenerative disorders, to date there have been no published reports regarding altered COX expression in disorders of the

peripheral nerve. Preliminary studies in this laboratory suggest that COX-2 protein abundance is significantly elevated in the sciatic nerve of STZ-D rats.³⁰⁴

The COX Pathway and Programmed Cell Death

Alterations of the COX-2 pathway have been implicated in the development of PCD. For example, it has been shown that induction of COX-2 mRNA and protein expression precede PCD in *in vivo* and *in vitro* models of neurodegeneration³⁰⁵ and that enhanced COX-2 protein expression promotes apoptosis in rat neocortex.³⁰⁶ Nonselective COX inhibitors, including flurbiprofen, which block predominantly the COX-1 pathway, have been shown to upregulate COX-2 gene expression and facilitate flux through this pathway. This has been linked to the induction of apoptosis in cultured rat gastric cells by a mechanism that involves increased oxidative stress.³⁰⁷ Although the presence of COX-2 induction in neurodegenerative conditions associated with PCD has been documented,³⁰⁵ its functional significance is still uncertain. It is possible that enhanced COX-2 expression induces neurotoxicity via accumulation of ROS and/or metabolites other than PG.³⁰⁶ Although most of the published data report a direct causal relationship between COX-2 activation and neuronal PCD, some suggest that

COX-2 may be neuroprotective.³⁰⁸ For instance, COX-2 expression has been demonstrated to inhibit trophic withdrawal apoptosis in NGF-differentiated PC12 cells.³⁰⁹ It can be concluded, therefore, that the interrelationships of the COX-2 pathway and apoptosis are complex and poorly understood.

We have proposed a model to explain the interrelationships among hyperglycemia, oxidative stress, PCD, and altered COX pathway activity in the development of nerve conduction deficits (Fig. 44-3). Hyperglycemia (through increased glucose autooxidation, advanced glycation end product formation, and activation of the AR pathway) generates increased ROS. Increased ROS, via upregulation of NF- κ B, induces COX-2 expression, which facilitates the conversion of arachidonate to vasoconstrictory and proinflammatory PG, thereby favoring endoneurial ischemia and hypoxia. Increased flux through COX-2 may further promote the generation of ROS, resulting in a self-reinforcing cycle. ROS may promote PCD by diminishing neurotrophic support and inducing mitochondrial dysfunction, thereby leading to the release of cytochrome C and activation of the caspase cascade. Increased AR pathway activity and osmolyte depletion contribute to reduced (Na,K)-ATPase activity. Increased oxidative stress, endoneurial ischemia, reduced (Na,K)-ATPase activity, and PCD may result in NCV slowing.

FIGURE 44-3. Proposed interactions of hyperglycemia, oxidative stress, and the cyclo-oxygenase (COX) pathway in experimental diabetic neuropathy. Hyperglycemia through increased auto-oxidation, with subsequent formation of advanced glycation end products, and activation of the aldose reductase (AR) pathway, with secondary NADPH and taurine depletion, generates reactive oxygen species (ROS) and increases oxidative stress. Increased ROS, via modulation of NF κ B-induced COX-2 expression, which regulates the conversion of arachidonate to vasoconstrictory and proinflammatory prostaglandin (PG), precipitates the imbalance in thromboxane A₂ (TXA₂)/PGI₂ ratio, therefore favoring vasoconstriction and ischemia. Reciprocally, COX-2 upregulation increases the rate of PGG₂ to PGH₂ conversion and ROS generation, further exacerbating oxidative stress. ROS may promote programmed cell death (PCD) by diminishing the nerve growth factor (NGF) neurotrophic support and by inducing mitochondrial dysfunction, which is thought to lead to caspase activation and cytochrome C release. Increased AR pathway activity and osmolyte depletion contribute to reduced (Na,K)-ATPase activity. Increased oxidative stress, endoneurial ischemia, reduced (Na,K)-ATPase activity, and PCD may result in nerve conduction velocity (NCV) slowing.

Neurotrophic Growth Factors and Diabetic Neuropathy

Neurotrophic growth factors modulate neuronal outgrowth during development and sustain innervation thereafter. In the mature animal, neurotrophins define the neuronal phenotype and promote local regeneration. An important function of the neurotrophins is to regulate the expression of phenotypic neuropeptides, including substance P and calcitonin gene-related peptide (CGRP), in adult DRG neurons. After nerve injury in the adult, they promote local neurite sprouting and regeneration.³¹⁰ Thus, blunting of these neurotrophic responses could mediate diabetic neuropathy if insulin deficiency and/or hyperglycemia (1) decreased growth factor synthesis by target organs or supporting cells, (2) disrupted retrograde transport of growth factors to the neuronal cell body, (3) affected the signal transduction mechanism(s) at the level of the Trk receptors or more downstream signaling cascades, or (4) promoted neuronal cell death.³¹¹

Mature Schwann cells also synthesize and express growth factors and growth factor receptors during neural development and regeneration,³¹² including NGF,³¹³ ciliary neurotrophic factor (CNTF), a small polypeptide originally purified from chick and rabbit sciatic nerve,³¹⁴ and insulin-like growth factor-I (IGF-I).³¹⁵ The neurotrophin family³¹⁶ has been expanded to include three additional neurotrophic factors, namely, brain-derived neurotrophin factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4/5 (NT-4/5).

Recently, the roles of neurotrophins have been explored using knockout mice models. Deletion of the high-affinity NGF receptor Trk A in mice results in extensive loss of sympathetic ganglionic neurons and small neural crest-derived sensory neurons (nociceptive C neurons).^{317,318} NT-3 knockout animals are deficient in both type 1a sensory afferents and muscle spindles, whereas BDNF and NT-4/5 null mutants lack neural placode-derived sensory cranial ganglia.³¹⁸

One of the best characterized growth factors is nerve growth factor (NGF), which is relatively specific for sensory and autonomic neurons and their axonal processes. NGF production and gene expression in autonomic and sensory neuronal targets vary reciprocally with the density of innervation by NGF-sensitive neurons.³¹⁹ In the rat heart, for example, high levels of NGF mRNA and protein are found in the densely innervated atria, but not in the more sparsely innervated ventricles, although regional ventricular differences have not been reported.³²⁰ Peripherally synthesized NGF is retrogradely transported by the axon from target organs to neuronal cell bodies for normal maintenance and regeneration of the peripheral nervous system. Ganglionic NGF is required for signal transduction, neurotransmitter synthesis, protein phosphorylation, methylation, and gene expression of ras-like proteins in sympathetic and sensory neurons.³²¹ Retrograde axonal transport is an important modulator of target tissue NGF. For example, total sympathetic denervation in adult rats produces high NGF protein levels in the heart,³²² without affecting tissue mRNA levels.^{322,323} NGF has antioxidant properties^{324,325} and protects sympathetic neurons from ROS-mediated PCD.³²⁵

Another family of growth factors thought to be important in the pathogenesis, and potentially the treatment, of diabetic neuropathy³²⁶ is the IGFs. IGF-I and IGF-II are polypeptides essential for normal fetal, neonatal, and pubertal growth. IGFs share many important neurotrophic properties with NGF and have neurotrophic actions in sensory sympathetic^{326,327} and motor neurons. These actions can all be affected by diabetes.³²⁸

IGFs are presently the only known neurotrophic factors that are found in nerve and muscle and are capable of supporting both sensory and motor nerve regeneration in adult animals.^{328,329} Glioblastoma, but not neuronal, cells express IGF-II mRNAs,³³⁰ unlike IGF-I which is expressed by both.³³⁰ Both IGF-I and -II increase the numbers of cells with neurites and the lengths of neurites in cultured human neuroblastoma cells³³¹ and cultured spinal cord motor neurons³³²; they also act as mitogens for the former. IGF receptors are found on the shafts and terminals of axons.³³²

Six IGF binding proteins (BPs) regulate the action of the IGFs³³³ and serve as possible targets for disruption by diabetes. IGFBP-II preferentially binds IGF-II and is the predominant IGFBP in the CNS and CSF.³³⁴ IGFBP-III, which binds both IGF-I and -II, is the principal form found in the circulation. Sites of production of IGFBPs include the neurons and glia.^{327,333} Local production of IGFs and their binding proteins may stimulate nerve fiber regeneration.^{329,335–337} Local production of IGF is probably important in stimulating regeneration, as IGFBPs would tend to block more distal effects.

Neurotrophins bind to a family of tyrosine kinase receptors called Trks (tropomyosin-related kinases).³³⁸ NGF binds to the high-affinity receptor Trk A, whereas Trk B serves as the receptor for both BDNF and NT-4/5, and Trk C binds NT-3. However, neurotrophins can bind and activate more than one receptor. Additionally, an abundant "low"-affinity receptor, termed p75, binds all the neurotrophins.³³⁹ This receptor may serve to modulate neurotrophin sensitivity³³⁹ and determine the survival requirements of mature neurons to the neurotrophins, particularly NGF.³⁴⁰ p75 may present neurotrophins to high-affinity receptors on the growing axons³³⁹ since it is upregulated by NGF,³⁴¹ axonal injury,³⁴² and collateral sprouting³⁴ and is expressed in target fields during their innervation.³⁴⁴

NGF receptors are expressed by Schwann cells during normal development but decline fivefold with maturation,³⁴⁵ and NGF production remains suppressed as long as axonal integrity and contact are maintained.³⁴⁶ Schwann cell NGF receptor expression is increased in human neuropathies associated with active nerve fiber degeneration.³⁴⁷ IGF-I immunoreactivity is also present in Schwann cell cytoplasm, is increased by sciatic nerve transection,³¹⁵ and enhances regeneration in a dose-dependent fashion in lesioned sciatic nerve.³⁴⁸ The expression of IGF-I and its receptor is markedly suppressed in axotomized diabetic nerve, and this change is associated with significantly impaired nerve fiber regeneration.³⁴⁹ In STZ-D rats, serum IGF-I levels are diminished,^{337,350} as is IGF-I mRNA in liver, kidney, lung, heart, and peripheral nerves.^{337,349,351} Thus blunted local neurotrophic effects may contribute to the pathogenesis of diabetic neuropathy, but the magnitude and details of this effect remain to be clarified.

An increasing number of studies have explored the effects of diabetes on neurotrophism in both animal models of DPN and humans. In diabetes, small changes in endogenous NGF levels may be of pathophysiologic significance since endogenous NGF levels are limited,³⁵¹ and their NGF receptors are unsaturated.³¹⁹ In diabetic rodents, endogenous NGF levels are reduced in some sympathetically innervated target organs,³⁵¹ including the sciatic nerve³⁵¹ and submandibular glands (the latter displaying decreasing NGF in the superior cervical ganglion).³⁵² In some target tissues, however, including the atria and ventricles, NGF content increases after the induction of diabetes, which may reflect impaired axonal transport or possibly increased regional synthesis.^{351,353}

Retrograde axonal flow of NGF to the cell bodies is altered in STZ-D rats.^{353,354} During experimentally induced diabetes, for

example, retrograde axonal transport of NGF along the mesenteric nerves (which supply the alimentary tract) to the superior mesenteric ganglion is reduced by approximately half,³⁵⁴ and these nerves can develop a distal diabetic axonopathy. In a similar fashion, NGF transport is decreased in diabetic somatic sensory neurons.³⁵⁵ Decreased NGF transport is a component of a generalized transport dysfunction in diabetes that includes proteins, glycoprotein, and neurotransmitters.³⁵⁴

Compared with NGF, considerably less is known about the effects of diabetes on other neurotrophins; IGF expression and/or action also appears to be altered in diabetes in both rodents and humans. Schwann cells from genetically diabetic rodents express lowered amounts of IGF-I, IGF-I-receptor (IGF-IR), and NGF.³⁵⁰ In streptozocin-treated rats, there is a decrease in serum IGF-I levels^{350,356,357} and a reduction in IGF-I mRNA in sciatic nerve, liver, kidney, lung, and heart.^{350,358–361} Recently, a 30–50% decrease in NT-3 and NT-4/5 gene expression was reported in nerves from rodents with experimental diabetes, whereas BDNF was undetectable.³⁶² Levels of NT-3 are decreased in the leg muscles from diabetic rodents, and its administration is reported to increase the NCV of sensory nerves.³⁶³

Abnormal neurotrophin receptor expression and/or sensitivity may play an important role in mediated impaired neurotrophic support. In lumbar DRG of diabetic rats, levels of Trk A mRNA, the 110-kD receptor protein,^{364,365} and p75 gene expression³⁶⁶ have been reported to be reduced. Others, however, have reported that DRG-immunoreactive Trk A is not affected by diabetes. NGF gene expression is regulated by glucose-sensitive signal transduction pathways,³⁶⁷ adrenergic mechanisms,³⁶⁸ and oxidative stress.³⁶⁹

Chronic oxidative stress depletes NGF by inhibiting protein synthesis³⁶⁹ and may downregulate NGF receptor expression, sensitivity, and transport.^{369,370} The chain-breaking antioxidant α -lipoic acid may stimulate NGF synthesis³⁷¹ and can prevent NGF protein depletion in sciatic nerve³⁷⁰ and myocardium of STZ-D rats (Stevens, personal observations). α -Lipoic acid augments NGF-mediated substance P release in STZ-D rats³⁷⁰ above that of equivalent correction of nerve NGF protein content by exogenous rhNGF alone, perhaps implicating oxidative stress in the downregulation of the NGF sensitivity that complicates diabetes. Some NGF transport defects can be corrected in the diabetic rat by treatment with ARIs, suggesting that increased polyol pathway flux may contribute to these axonal transport defects. In subjects with DAN, serum NGF levels are reduced,³⁷² and in patients with early diabetic neuropathy, decreased skin axon reflexes, mediated by small sensory fibers, correlate with loss of NGF expression in keratinocytes. In patients with diabetic neuropathy,³⁷³ no change in p75 NGF receptor expression has been reported in sural nerve biopsy specimens.

Limited evidence suggests that neurotrophin treatment may be effective in the management of DPN. In experimental diabetes, NGF treatment protects against the development of diabetic sensory neuropathy^{374,375} and ameliorates diabetes-induced decreases in neuropeptide levels *in vivo*³⁷⁶ and *in vitro*.³⁷⁷ NGF-treated diabetic rodents retain the ability to respond to noxious thermal stimuli and express normal neuropeptide levels.³⁷⁵ NGF has been reported to reverse defects in myelinated nerve fiber morphology such as myelin thickness and to increase CGRP and substance P in the DRG and dorsal horn of the spinal cord of diabetic rats. The defects in p75 transport and protein content but not mRNA are reversed by rhNGF.³⁶⁴ In lumbar DRG, reported deficits of Trk A

mRNA and the 110-kD receptor protein are not sensitive to rhNGF.³⁶⁴ DRG-immunoreactive Trk A has been reported to be decreased by NGF in healthy control rats.³⁷⁸ NGF has been reported to restore abnormal sensory C-fiber function in transgenic diabetic mice.³⁷⁹ Treatment with 4-methylcatechol, which stimulates endogenous NGF synthesis, also ameliorates neuropathy in streptozocin-treated rodents.³⁸⁰ Treatment of STZ-D rats with IGF-I protects against the development of diabetic neuropathy and restores normal nerve function.^{311,328}

Clinical trials in humans, however, have been disappointing to date. For example, a randomized, placebo-controlled trial of s/c NGF did not confirm any beneficial effects on neuropathic symptoms or abnormalities on clinical examination, but small nerve fiber function was inadequately assessed.³⁸¹ In humans, studies evaluating the potential of IGF-I administration as a treatment for diabetic neuropathy have been hampered by the development of toxicity.

SUMMARY AND CONCLUSIONS

Theories of the pathogenesis of diabetic neuropathy continue to evolve; the disease is considered to involve acute functional abnormalities in nerve fibers, followed by more chronic nerve fiber atrophy, injury and loss associated with microvascular dysfunction, and blunted nerve fiber regeneration. These abnormalities can be traced to the metabolic effects of hyperglycemia and/or other effects of insulin deficiency on the various constituents of peripheral nerve, its supporting connective tissue and vascular elements, and possibly the autonomic innervation that controls the endoneurial microvasculature. The polyol pathway, oxidative stress, and/or non-enzymatic glycation affecting one or more cell types in the multicellular constituents of peripheral nerve appears to have an inciting role. The potentially important roles of other factors, such as possible direct neurotrophic effects of insulin and insulin-related growth factors, remain to be explored, as do the more complex and indirect effects of glucose metabolism via the vascular elements of peripheral nerve.

ARIs, which have been proposed as the first mechanistically based treatment for diabetic neuropathy, constitute only the first of many such therapies, each directed against one or more elements in the complex pathogenetic process responsible for diabetic neuropathy. Despite the setbacks of recent clinical trials, the ability of biochemically effective ARIs to improve nerve function in diabetic patients and the evidence that they improve nerve structure and function in patients with early diabetic neuropathy have established the polyol pathway as one likely mediator of nerve dysfunction and damage in human diabetes.

The challenge that lies ahead will be the development of potent therapeutic interventions that can safely be given at high enough doses to prevent the diverse metabolic consequences of hyperglycemia. Animal studies indicate that this may most rapidly be achieved by using combinations of agents to block the diverse metabolic pathways mediating glucose toxicity. However, the evidence that improved metabolic control can prevent the development of clinical neuropathy⁸³ argues strongly for the hypothesis that hyperglycemia and/or insulin deficiency is at the root of diabetic neuropathy and that improved metabolic control should protect against the development (and probably progression) of the disease.

Somatosensory Neuropathy

Eva L. Feldman

Martin J. Stevens

James W. Russell

Douglas A. Greene

First identified as a clinical entity more than 200 years ago,¹ diabetic neuropathy is now the most common neuropathy in the Western world.²⁻⁴ Diabetic neuropathy carries a high morbidity and is the leading cause of nontraumatic limb amputations.⁵ The Diabetes Control and Complications Trial (DCCT) confirmed the theory that diabetic neuropathy is the result of sustained hyperglycemia.⁶ Diabetic neuropathy complicates the secondary forms of diabetes, such as those resulting from pancreatectomy, nonalcoholic pancreatitis, and hemochromatosis, a finding that supports hyperglycemia as the common underlying mechanism for diabetic neuropathy.^{7,8}

Diabetic neuropathy is actually composed of several distinct syndromes with differing anatomic distribution, clinical course, and possibly underlying pathogenetic mechanism(s). The overall prevalence of diabetic neuropathy is uncertain, but generally is considered to be approximately 50%, with a clinical course that parallels the duration and severity of hyperglycemia in both type 1 or insulin-dependent diabetes mellitus (T1DM) and type 2 or non-insulin-dependent diabetes mellitus (T2DM).^{3,9-16} There are several well-explored metabolic abnormalities in diabetic nerves that result from hyperglycemia and are therefore potential initiating or contributing factors in the pathogenesis of diabetic neuropathy.^{8,17-19} The role of specific glucose-linked biochemical processes such as enhanced oxidative stress, polyol-pathway activation, and nonenzymatic glycation in the pathogenesis of neuropathy is the basis of not only intensive investigation, but also the development and testing of new forms of therapy for patients with or at risk of developing diabetic peripheral neuropathy. These abnormalities may occur in several of the cellular constituents of peripheral nerves and their supporting tissues, and may thereby partially account for some of the variability of clinical neuropathy in various subgroups and individual patients with diabetes. Understanding these potential pathogenetic mechanisms is essential for the effective management of diabetic neuropathy.²⁰ These concepts are more fully discussed in Chap. 44 on pathogenesis.

There are three general therapeutic approaches to the treatment of diabetic neuropathy. Preventive management strategies (e.g., education and hygiene) are designed to deal with potential risk factors for the development of neuropathy.²¹ Palliative management strategies are designed to alleviate specific symptoms of diabetic neuropathy (e.g., pain, foot deformities, or ulcers).^{22,23} Definitive

therapeutic strategies are targeted against specific pathogenetic components of diabetic neuropathy.²³⁻²⁵ Currently, glycemic control is the only effective definitive therapy.²⁶ The development of future adjunct therapies to prevent and potentially reverse the neurologic damage that underlies the clinical manifestations of diabetic neuropathy awaits clearer understanding of the responsible pathogenetic mechanisms²⁷ (see Chap. 44).

EPIDEMIOLOGY, IMPACT, AND SCOPE OF DIABETIC NEUROPATHY

Estimates of the impact and frequency of diabetic neuropathy are dependent on the choice of terminology, diagnostic criteria, and study populations. Minor paresthesias may constitute diabetic neuropathy in one study, while others may employ much more rigid criteria, including electrophysiology and quantitative sensory testing. The discrepancies in prevalence estimates reflect the different criteria used to diagnose neuropathy. The sensitivity, specificity, and reliability of simple objective measures to diagnose neuropathy in a person with diabetes are still controversial.²⁸⁻³¹ Nevertheless, certain generalizations are clear from the available data; specifically, neuropathy is a frequent complication of diabetes, and estimated prevalence rates are on average 50% and rise with advancing age.³²

In a frequently cited prospective study of over 4400 diabetic outpatients, Pirart reported an overall 12% prevalence rate of diabetic neuropathy in patients with newly diagnosed diabetes.³³ The incidence of neuropathy increased with the duration of diabetes, and after 25 years of diabetes, over 50% of patients had diabetic neuropathy.³³ Several cross-sectional multicenter studies of a mixed group of type 1 and 2 diabetic patients have yielded similar results. In the United Kingdom, 6487 diabetic patients were examined for the presence of neuropathy by a simple assessment of ankle reflexes, vibration, pinprick, and temperature sensation, coupled with a 9-point symptoms score. The reported prevalence of neuropathy was 5% in the 20- to 29-year-old group and increased with age, reaching 44.2% in patients between 70 and 79 years of age.¹² A simple screening tool examining ankle reflexes and great toe sensation³⁴ was administered to 8757 diabetic patients, and

32.3% of patients had abnormalities consistent with diabetic neuropathy.⁹ Severity of neuropathy was then graded in the 2033 neuropathic patients using a quantitative assessment of strength, sensation, reflexes, and electrophysiology. Over one-half of all patients had mild to moderate neuropathy, while 20% had borderline and 12% severe neuropathy; in each category, the severity of neuropathy increased with age and duration of diabetes.⁹ A similar increase in severity and prevalence of neuropathy with age and duration of diabetes was reported among Spanish patients.³⁵ In the population-based Rochester Diabetic Neuropathy Study, which commenced in 1986, 54% of type 1 and 45% of type 2 diabetic patients had polyneuropathy,¹¹ defined as two or more abnormalities from quantitative assessment of symptoms, signs, sensation, autonomic function, and nerve conduction studies.

Several studies evaluated the presence of neuropathy in patients with either T1DM or T2DM. In the Diabetes Control and Complication Trial (DCCT), a cohort of 278 healthy type 1 diabetic patients were examined for the presence of neuropathy, defined as an abnormal neurological examination plus either abnormal nerve conduction studies in two nerves or abnormal autonomic function testing. Using these criteria, 39% of patients had some clinical manifestation of neuropathy.³⁶ Similarly, in the Pittsburgh Epidemiology of Diabetes Complications Study, the prevalence of neuropathy in T1DM patients was 18% in patients 18–29 years of age, compared to 58% in the >30-year-old group.³⁷ In the EURO-DIAB complications study, 3250 T1DM patients were examined from 16 European countries, and the overall prevalence of diabetic neuropathy was 28%, with significant correlations with age, duration of diabetes, and quality of metabolic control.¹³ Using abnormal nerve conduction studies to define subclinical neuropathy, 87% of type 1 diabetic children were neuropathic, with the majority of abnormalities in the lower limbs.³⁸ Similar statistics emerge from studying T2DM patients. In a longitudinal study, 8.3% of type 2 patients had neuropathy upon diagnosis of diabetes, with an increased prevalence to 42% after 10 years of diabetes.¹⁰ A separate prospective study of type 2 patients reported that 22% developed diabetic neuropathy after 4 years.³⁹ In a cohort of type 2 diabetic patients with a mean duration of 12 years of diabetes, 49% had diabetic neuropathy.⁴⁰

This high prevalence of diabetic neuropathy is associated with significant morbidity, including recurrent foot infections, ulcers, and amputations.^{41,42} The national annual direct cost of diabetic foot ulcers in the United States is estimated to be \$5 billion with an indirect cost of \$400 million.⁴³ Between 1995 and 1996, the average Medicare expenditure for a diabetic patient was \$15,309, compared to \$5,226 for Medicare patients in general, and 25% of these dollars went to the treatment of foot ulcers.⁴³ On average, 15% of patients with diabetic neuropathy require an amputation, making diabetic neuropathy the most common cause of nontraumatic amputations in the Western world.⁴¹ Thus diabetic neuropathy is generally conceded to be an extraordinarily common complication of diabetes, causing significant morbidity and carrying a large financial burden.

CLASSIFICATION OF DIABETIC NEUROPATHY

Diabetic neuropathy can be classified into two stages or classes, *subclinical* (class I) and *clinical* (class II) (Table 45-1).⁴⁴ *Subclinical diabetic neuropathy* consists of evidence of peripheral nerve dysfunction such as slowed motor and sensory nerve conduction, elevated

TABLE 45-1. Classification and Staging of Diabetic Neuropathy

Class I: Subclinical Neuropathy*

- A. Abnormal Electrodiagnostic Tests (EDX)
 1. Decreased nerve conduction velocity
 2. Decreased amplitude of evoked muscle or nerve action potential
- B. Abnormal Quantitative Sensory Testing (QST)
 1. Vibratory/tactile
 2. Thermal warming/cooling
 3. Other
- C. Abnormal Autonomic Function Test (AFT)
 1. Diminished sinus arrhythmia (beat-to-beat heart rate variation)
 2. Diminished sudomotor function
 3. Increased pupillary latency

Class II: Clinical Neuropathy

- A. Diffuse Neuropathy
 1. Distal symmetric sensorimotor polyneuropathy
 - a. Primarily small-fiber neuropathy
 - b. Primarily large-fiber neuropathy
 - c. Mixed
 2. Autonomic neuropathy
 - a. Abnormal pupillary function
 - b. Sudomotor dysfunction
 - c. Genitourinary autonomic neuropathy
 - (1) Bladder dysfunction
 - (2) Sexual dysfunction
 - d. Gastrointestinal autonomic neuropathy
 - (1) Gastric atony
 - (2) Gallbladder atony
 - (3) Diabetic diarrhea
 - (4) Hypoglycemia unawareness (adrenal medullary neuropathy)
 - e. Cardiovascular autonomic neuropathy
 - f. Hypoglycemia unawareness
 - B. Focal Neuropathy
 1. Mononeuropathy
 2. Mononeuropathy multiplex
 3. Plexopathy
 4. Radiculopathy
 5. Cranial neuropathy

* Neurological function tests are abnormal but no neurological symptoms or clinically detectable neurological deficits indicative of a diffuse or focal neuropathy are present. Class I, Subclinical Neuropathy, is further subdivided into class Ia if an AFT or QST abnormality is present, class Ib if EDX or AFT and QST abnormalities are present, and class Ic if an EDX and either AFT or QST abnormalities or both are present.

sensory perception thresholds that occur in the absence of clinical signs, and/or symptoms of diabetic neuropathy. *Clinical diabetic neuropathy* consists of the superimposition of symptoms and/or clinically detectable neurologic deficits (Table 45-1). Clinically overt diabetic neuropathy manifests itself as the presence of one or more of the individual clinical syndromes, representing either diffuse or focal neuropathy. Although each syndrome has a characteristic presentation and clinical course, they frequently coexist in the same patient, often making classification of individual cases difficult.

Diffuse clinical diabetic neuropathy refers to distal symmetric sensorimotor polyneuropathy and autonomic neuropathy. *Distal symmetric polyneuropathy* is the most commonly recognized form of diabetic neuropathy and features sensory deficits and symptoms

that overshadow motor involvement.^{31,45} Sensory deficits initially appear in the most distal portions of the extremities and progress proximally in a “stocking-glove” distribution, in the most advanced cases forming vertical bands on the chest as distal portions of truncal nerves become involved.^{32,46} The signs, symptoms, and neurologic deficits of distal symmetric polyneuropathy vary depending on the classes of nerve fibers. Loss of large sensory and motor fibers leads to a loss of light touch and proprioception and produces muscle weakness, while loss of small fibers diminishes pain and temperature perception and produces paresthesias, dysesthesias, and/or neuropathic pain.^{8,32,47} Diminished or absent deep-tendon reflexes, especially the Achilles tendon reflex, are often an early indication of otherwise mild asymptomatic neuropathy. Undetected but more advanced asymptomatic neuropathy may first present with late complications such as ulceration or neuroarthropathy (Charcot’s joints) of the foot.⁴⁸ The other diffuse form of clinical diabetic neuropathy is *diabetic autonomic neuropathy* (see Chap. 46). This often but not always accompanies distal symmetric polyneuropathy and can impair virtually any sympathetic or parasympathetic autonomic function.^{20,49}

Cardiovascular autonomic neuropathy first compromises cardiac parasympathetic function, diminishing the normal bradycardic responses to sleep and deep inspiration. With progression, sympathetic cardiac and peripheral vascular denervation occurs, interfering with normal cardiovascular response to exercise and sensitizing the heart to circulating catecholamines, which may predispose to tachyarrhythmia and sudden death.⁵⁰ Autonomic neuropathy leading to respiratory arrest has also been implicated in sudden death (see Chap. 46). *Gastrointestinal autonomic neuropathy* can involve virtually the entire length of the gastrointestinal tract.⁵¹ It contributes to nonspecific gastrointestinal tract symptoms that afflict the majority of diabetic patients. Esophageal motility impairment and reflux, decreased vagally mediated gastric acid secretion, and delayed gastric emptying produce anorexia, nausea, vomiting, early satiety, and postprandial bloating and fullness.⁵¹ Diabetic enteropathy encompasses the clinical syndromes of diabetic constipation, diabetic diarrhea, and fecal incontinence, which all reflect widespread abnormalities in the intrinsic and extrinsic intestinal autonomic nervous system.⁵² *Genitourinary autonomic neuropathy* includes retrograde ejaculation, neuropathic erectile impotence, deficient vaginal lubrication leading to dyspareunia, and diabetic cystopathy.⁵³ Neuropathic impotence is generally but not always accompanied by other manifestations of diabetic neuropathy (see Chap 46).⁵³

Autonomic sudomotor dysfunction produces an asymptomatic distal anhidrosis in a stocking-glove distribution similar to that of distal symmetric polyneuropathy. This diminished thermoregulatory reserve predisposes to heatstroke and hyperthermia, and produces a compensatory central hyperhidrosis that is often bothersome to the patient.⁴⁹ All forms of autonomic neuropathy are addressed in detail in Chap. 46.

The *focal forms of diabetic neuropathy* correspond to the distribution of single or multiple peripheral nerves (mononeuropathy and mononeuropathy multiplex), cranial nerves, regions of the brachial or lumbosacral plexuses (plexopathy), or the nerve roots (radiculopathy). With the exception of peripheral nerve mononeuropathies, these focal forms of diabetic neuropathy are relatively uncommon.^{11,20} They are frequently of sudden onset, are generally but not always self-limited, and tend to occur in older age groups.²⁰ Among cranial nerves, the third cranial nerve is often affected, presenting with unilateral pain, diplopia, and ptosis with pupillary

Table 45-2. Diabetes Mellitus: Potential Peripheral Nervous System Complications

sparing, in a syndrome termed *diabetic ophthalmoplegia*. Diabetic ophthalmoplegia may occur in the absence of other manifestations of diabetic neuropathy, and may be bilateral, recurrent, or both.⁵⁴ Femoral neuropathy, typically seen in older male type 2 diabetic patients, often involves motor and sensory deficits at the level of the lumbar plexus or lumbar roots as well as the femoral nerve, with the relative excess of motor versus sensory involvement differentiating diabetic femoral neuropathy from that seen in other conditions.⁵⁵ Thoracic radiculopathies present as band-like thoracic or abdominal pain that is often misdiagnosed as an acute intrathoracic or intra-abdominal emergency.⁵⁶ The more common mononeuropathies mimic the compression neuropathies seen in nondiabetic individuals, such as carpal tunnel syndrome or ulnar neuropathy.⁵⁷ In summary, distal symmetric polyneuropathy and autonomic neuropathy are common, diffuse, and generally progressive disorders, whereas the focal neuropathies are rare, sudden in onset, often self-limited, and occur primarily in older patients with diabetes. These various forms of diabetic neuropathy are discussed in more detail below and are listed in Table 45-2.

RELATIONSHIP OF NEUROPATHY TO THE DURATION AND METABOLIC SEVERITY OF DIABETES IN MAN

The relationship of diabetic neuropathy to the severity and duration of hyperglycemia has important therapeutic as well as pathogenetic implications. The close link between the severity and/or duration of hyperglycemia with the development of diabetic neuropathy supports intensified glycemic control and implicates glucose or insulin-related metabolic factors as important pathogenetic elements in the disease process. In the Stockholm Diabetes Intervention Study, intensified insulin treatment of T1DM patients prevented the nerve conduction slowing that occurred after 5 years in the regular treatment group,⁵⁸ with continued benefit evident at 10 years.⁵⁹ The Diabetes Control and Complications Trial (DCCT) provides even stronger evidence for the importance of insulin deficiency, hyperglycemia, or both in the pathogenesis of diabetic neuropathy.⁶⁰ Intensive diabetes treatment designed to lower blood glucose to as close to the normal range as possible in nonneuropathic subjects with T1DM was, after 5 years, able to reduce the prevalence of clinical diabetic neuropathy confirmed by abnormal nerve conduction or autonomic function by 60%.⁶⁰

While T2DM is nearly 10 times more common than T1DM, there exists only one prospective trial of type 2 patients and the effects of glycemic control on the development of neuropathy. In the VA cooperative study, 153 men with an average age of 60 and an average known diagnosis of diabetes of 7.8 years were randomly assigned to standard or intensive therapy. After 24 months there was no difference in the overall prevalence of peripheral or autonomic neuropathy.⁶¹ However, these results must be considered in the context of the several large epidemiologic and population-based studies (discussed at the beginning of this chapter) that reveal a strong highly significant association between hyperglycemia and neuropathy.⁶² Thus, a large long-duration prospective trial of both men and women with T2DM is required to conclusively address this question. Notwithstanding this fact, the generally held belief is that longer duration and greater extent of hyperglycemia predispose to the development of neuropathy in T2DM patients in a manner similar to that of T1DM patients.^{14,16}

The onset of clinically overt diabetic neuropathy in an individual patient is an unpredictable event. This is true despite the close epidemiologic association between clinical neuropathy and the duration and severity of hyperglycemia in populations of diabetic patients. The sometimes-reported “paradoxical precipitation of neuropathy following institution of good control” refers primarily to the acute onset of pain that likely reflects repair and regeneration of damaged nerve fibers. Unfortunately, clinical neuropathy was not reassessed in the DCCT until the fifth year after initiation of intensive diabetes therapy,⁶⁰ so the temporal association between the institution of diabetes control and the development of neuropathy could not be determined.

The onset of neuropathy may also be influenced by other independent variables such as genetic, nutritional, and toxic factors.^{13,63} Alcohol consumption, even well within the socially accepted norms, appears to be a risk factor for neuropathy.^{36,64} In diabetic subjects with absent or very mild clinical neuropathy, nerve conduction parameters are also affected by a variety of features other than the severity and duration of diabetes. These variables include age, height, and gender, as well as pubertal state at the time of diagnosis of diabetes.^{36,65}

DIAGNOSIS AND STAGING OF DIABETIC NEUROPATHY

There are three recent areas of active investigation aimed at improving the diagnosis and classification of diabetic neuropathy: (1) the use of quantitative sensory testing and electrodiagnostic studies to quantify neural damage, especially as part of large clinical trials, (2) the use of standardized criteria to diagnose and monitor neuropathy, especially in a research setting, and (3) the development of simple neuropathy screening tools for use in outpatient clinics. This section discusses each area and presents an outpatient program for the diagnosis of neuropathy in the practitioner's office.

Quantitative Sensory Tests

Quantitative tests of nerve function are valuable in evaluating the extent, severity, natural history, and prevalence of diabetic neuropathy.⁶⁶ They may also identify patients with unrecognized subclinical or asymptomatic clinical (e.g., signs alone) diabetic neuropathy.²⁹ Sensory threshold measurements have the advantage over a clinical sensory examination in that reproducible, quantita-

tive, and graded stimuli are administered to the patient. Reproducible algorithms for objectively testing and assessing thresholds are defined and compared to well-established normative values.⁶⁷ Abnormal sensory thresholds correlate with the presence of diabetic neuropathy in groups of diabetic patients and in individual patients.⁶⁸

There are several commercial instruments available for the evaluation of quantitative sensory perception thresholds. The sensory stimuli used in these instruments include thermal, touch-pressure, vibratory, tactile, and electrical stimuli.⁶⁶ Older methodology and instruments used a ramp technique or a method-of-limits technique, both of which are confounded by response bias. A true alternative forced-choice algorithm minimizes response bias. Stimulus and nonstimulus episodes are presented in pairs, and the patient must identify which episode contained the stimulus. Established algorithms for all commercially available products define threshold as the minimum stimulus correctly detected by the patient 50% of the time.⁶⁶ A computer-assisted sensory examination (CASE) is now commercially available and represents the best standardized method for sensory perception threshold testing.⁶⁹ It eliminates bias and is the prototype for many of the simpler commercially available products that are less expensive and can be used with a minimal amount of training. Confounding variables that influence sensory perception threshold include age, obesity, ischemia, skin temperature, patient alertness, room ambience, and test anxiety.⁶⁶

Vibratory Perception Threshold

Vibratory perception threshold measures large-nerve fiber integrity and perception and is normally poorer in the lower extremity than the upper extremity. It may be abnormal in the absence of clinical symptoms or deficits and may therefore indicate subclinical neuropathy.⁶⁶ More frequently, abnormalities of vibration perception are associated with the loss or reduction of the Achilles tendon reflex. Abnormal vibratory perception threshold is more common than abnormal touch-pressure and temperature threshold in diabetic individuals, and it may therefore be a more sensitive index of subclinical neuropathy.⁷⁰ Patients with impaired vibratory sensation are more prone to develop foot ulceration, lending clinical significance to the impairment of vibratory perception.⁷¹⁻⁷³ Thus vibratory perception threshold is a sensitive and clinically significant index of large-nerve fiber involvement in patients with diabetes.^{30,70,71,73}

Thermal Perception Threshold

Thermal perception threshold reflects small-nerve fiber integrity.⁶⁶ Because diminished temperature perception predisposes to accidental burns in diabetic individuals, it has important clinical implications. Both warming and cooling can be used to measure thermal perception, although the warming method may have a higher degree of sensitivity than cooling.⁷⁴ Both methodologies have been well validated and are easy to perform.^{74,75}

Electrodiagnostic Studies

Electrodiagnostic tests have widespread application and are reliable, reproducible measures of peripheral nervous system function relative to disorders of nerve, muscle, and neuromuscular junction.⁷⁶ They are objective measures that are relatively independent of patient effort or cooperation.⁷⁶ Nerve conduction studies and

needle electromyography are well accepted for the evaluation of diabetic neuropathy, including recent use in sequential studies to evaluate disease progression or response to treatment.^{46,77} These are sensitive measures, able to detect abnormalities in diabetic patients that may not be clinically apparent.⁷⁷

Test Description

The term *electromyography* technically refers to the needle electrode examination, but it often is used in reference to both nerve conduction measures and the needle examination. Both are important components of the electrodiagnostic examination that have been used since the mid-1950s to evaluate patients with suspected diabetic neuropathy. They are described separately because they evaluate slightly different components of the peripheral nervous system, reflect different abnormalities, and have different applications depending on the question asked.

Nerve Conduction Studies

Nerve conduction studies^{76,78} are used to evaluate sensory and motor nerves. In these studies, measures of sensory nerve action potential (SNAP) or compound muscle action potential (CMAP) amplitude, distal latency, and conduction velocity are recorded. Amplitude measures are important in the evaluation of peripheral neuropathy, reflecting in part the size and number of nerve or muscle fibers.

Conduction velocity, as used in conventional electrodiagnostic studies, reflects transmission time in the largest myelinated nerve fibers. It is expressed as a conduction velocity (meters per second; m/s) between two points along the nerve, or as a terminal or distal latency (milliseconds) along a fixed distance at the end of the nerve. For motor conduction studies, the distal latency also includes a neuromuscular transmission latency. The conduction velocity reflects several physiologic components of peripheral nerve function, including nerve size, amount of myelin, nodal and internodal lengths, axonal resistance, and nerve temperature. In addition to the known pathologic findings of primary axonal loss and secondary demyelination and remyelination in diabetic neuropathy, there may be metabolic changes associated with reduced conduction velocity as well. The observation that nerve conduction velocity increased 6 hours after initiating normal glucose levels suggests that nonstructural changes at least partially account for conduction abnormalities in diabetic neuropathy.⁷⁹

Conduction over the entire motor nerve, including its proximal portion, can be approximated by F-wave latency measures. The F wave occurs after antidromic motor nerve stimulation, with resultant activation of a portion of the anterior horn cells from that nerve and transmission of an orthodromic response along those fibers. This response can be recorded directly from a muscle innervated by those fibers and the stimulation-to-response-onset latency determined. Conduction velocity abnormalities in diffuse disorders are accentuated by the long conduction distances, making abnormalities in F-wave latencies very sensitive measures of diabetic neuropathy, as well as in other conditions associated with diabetes, such as diabetic polyradiculopathy.

Needle Electromyography

Needle electromyography^{76,78} (EMG) may be the most sensitive indicator of axonal degeneration and may demonstrate abnormality in asymptomatic diabetic patients. Though quantitative measures of motor unit action potential recruitment, amplitude, duration, and configuration are difficult and unreliable compared with

nerve conduction measurements, the subjective determination of the presence or absence of fibrillation potentials or positive waves at rest is easily performed and reproducible. The presence of abnormal insertional activity is a very sensitive indicator of axonal degeneration. These may appear prior to development of clinical findings, and prior to development of nerve conduction velocity or SNAP amplitude abnormalities. Most patients feel that the needle examination is more uncomfortable than the conduction studies, and it is rarely used in sequential clinical trials because of poor tolerance. Its most important use in diabetic neuropathy is to document the presence or absence of superimposed diabetic polyradiculopathy, amyotrophy, plexopathy, or other peripheral nerve disorders.⁷⁷

Electrodiagnostic Evaluation of Diabetic Neuropathy

The techniques used in the electrodiagnostic evaluation of diabetic patients must be rigorous. Nerve conduction studies should be performed and reported, together with normal values, using standardized laboratory techniques.⁷⁶ Normal values usually are reported as three standard deviations from the mean when the data are normally distributed, or as a normal range or 99th percentile when the distribution is not Gaussian.⁷⁶ Different values exist for different age groups and some measures vary according to patient size (height, finger circumference, and limb length).⁷⁶ Using appropriately defined normal data, individual diabetic patients or groups of patients may be compared with population normal values.⁷⁷ One important source of variability in nerve conduction measurements relates to the influence of limb temperature on amplitude, distal latency, and conduction velocity.⁷⁶ Conventional practice is to warm cool limbs into the temperature range used for obtaining normal values, usually 32°–36°C.⁷⁷

Standard Evaluation and Interpretation

The electrodiagnostic examination of diabetic patients must be thorough because a variety of diabetes-related peripheral abnormalities exist, including mononeuropathy, mononeuritis multiplex, plexopathy, polyradiculopathy, and sensorimotor polyneuropathy (Table 45-2). A complete evaluation allows detection and quantification of the peripheral disorder, as well as identifying the predominant pathophysiology. Such an evaluation may allow patient classification into homogeneous groups for treatment trials (e.g., pure sensorimotor polyneuropathy versus polyradiculopathy or polyradiculoneuropathy), while simultaneously identifying patients with superimposed focal or multifocal lesions.

A standard evaluation can be outlined (Table 45-3), although the strategy differs depending on the severity of the disorder. When symptoms or signs are minimal, evaluation is directed toward the most sensitive or susceptible nerves.⁷⁷ In diabetic neuropathy, distal lower-extremity studies are more likely to be abnormal than upper-extremity studies, and sensory abnormalities are more common than motor abnormalities.⁷⁷ Absent lower-extremity responses cannot be used to document subsequent progression, and because of this, it is important to study less involved nerves.^{46,77,78,80}

The needle examination is used in several ways. As a sensitive indicator of axonal degeneration, it may demonstrate the only abnormality in an early diabetic neuropathy.⁷⁷ The electromyographer can also use needle electromyography to examine muscles inaccessible or poorly accessible to nerve conduction studies, including paraspinal, abdominal, and proximal extremity muscles. Abnormal findings in such muscles may provide evidence of polyradiculopathy (symptomatic or asymptomatic), amyotrophy,

TABLE 45-3. Polyneuropathy Protocol

I. Conduction Studies*	
A. General	
1.	Test most involved site if mild or moderate, least involved if severe.
2.	Warm limb if temperature is <32°C; monitor and maintain temperature throughout study.
3.	Use reproducible recording and stimulation sites (either fixed distances or standard landmarks).
4.	Use supramaximal percutaneous stimulation.
B. Motor Studies	
1.	Peroneal motor (extensor digitorum brevis); stimulate at ankle and knee. Record F-wave latency following distal antidromic stimulation.
2.	Abnormal, tibial motor (abductor hallucis); stimulate at ankle; record F-wave latency.
3.	If no responses: peroneal motor (anterior tibial); stimulate at fibula.
4.	Ulnar motor (hypotenar); stimulate below wrist and elbow. Record F-wave latency.
5.	Median motor (thenar); stimulate wrist and antecubital fossa. Record F-wave latency.
C. Sensory Studies	
1.	Sural sensory (ankle); may occasionally require:
a.	Needle recording
b.	Response averaging
2.	Median sensory (index); stimulate wrist and elbow. If antidromic response absent or focal entrapment suspected, record (wrist) stimulating palm.
3.	Ulnar sensory (5th digit); stimulate wrist. If antidromic response absent or superimposed on motor artifact, perform orthodromic study.
D. Autonomic Studies	
1.	Skin potential responses (palmar and plantar surfaces of hand and foot, respectively); stimulate contralateral median nerve.
E. Additional	
1.	Additional motor or sensory nerves can be evaluated if findings equivocal. Definite abnormalities should result in:
a.	Evaluation of opposite extremity
b.	Proceed to evaluation of specific suspected abnormality.
II. Needle Examination	
A. Representative Muscles	
1.	Anterior tibial, medial gastrocnemius, first dorsal interosseous (hand), and lumbar paraspinal muscles.
2.	If normal, intrinsic foot muscles should be examined.
3.	Any abnormalities should be confirmed by examination of at least one contralateral muscle.
B. Grading	
1.	Abnormal spontaneous activity should be graded subjectively [0–4] using conventional criteria.
2.	Motor unit action potential amplitude, duration, configuration, and recruitment graded subjectively.

* Recording sites are in parenthesis.

or other focal disorder.⁷⁶ The subjective interpretation of the results of needle electromyography also allows differentiation of acute, subacute, and chronic peripheral disorders. This may be useful in identifying evidence of residual abnormalities, independent from diabetic neuropathy.

There is a positive relationship between the electrodiagnostic and clinical examinations. Quantitative neurologic measures of sensation, including touch-pressure, vibration, and two-point discrimination, and muscle stretch reflexes and strength correlate with electrodiagnostic measures, including sensory evoked amplitudes and

motor conduction velocities.⁷⁶ Sural nerve morphology has also been compared with results from nerve conduction studies. Typical findings included loss of large and small myelinated nerve fibers, evidence of segmental remyelination and demyelination, and variable amounts of axonal degeneration. Comparing maximal measured sural conduction velocity with the diameter of the largest axons indicated that conduction velocities were 10–30% slower than expected, based on normal mean values, even in nerves with preserved large fibers.⁴⁶ The electrodiagnostic findings in the sural nerve were representative of findings in other nerves. It was concluded that such slowing was due to causes other than fiber loss, whereas more substantial slowing was related to degeneration of large fibers. The reported pathologic findings demonstrate that fiber loss is primary and demyelination with remyelination is secondary.^{81–83}

Subclinical Diabetic Neuropathy

Significantly reduced conduction velocity in asymptomatic, neurologically intact patients is not surprising and has been reported in several studies.^{46,77} Slowed conduction velocity may reflect segmental demyelination and remyelination without conduction block or substantial axonal degeneration, or it may reflect a metabolic abnormality in diabetic nerve. For example, mean motor conduction velocity differences of 4.6 m/s were found in diabetic patients compared to age-matched controls, averaged for upper- and lower-extremity nerves.⁸⁴ Other studies have demonstrated that loss of amplitude of sensory potentials is a sensitive indicator of subclinical involvement, followed by the appearance of fibrillation potentials.⁸⁵

Clinically Evident Diabetic Neuropathy

Conduction velocity slowing has been reported consistently, usually demonstrating a 5–13-m/s difference between diabetic patients with clinically evident neuropathy and age-matched control subjects.⁸⁶ The actual difference depends on the nerves studied, the severity of the neuropathy, and other factors, including glycemic control.

Sensory conduction abnormalities are more pronounced than motor abnormalities (greatest mean deviation from normal), and most pronounced in the distal lower extremities. The overall sensitivity of the electrodiagnostic evaluation has been studied by determining the frequency of abnormality for individual measures for 109 adult diabetic patients under 60 years of age with clinically apparent diabetic neuropathy. The percentage of patients demonstrating abnormality of individual test measures was as follows: abnormal sural amplitude, 91% (absent in 63%; reduced in 16%); abnormal needle examination of intrinsic foot muscles, 88%; reduced tibial and peroneal motor conduction velocities, 75%; reduced median and ulnar motor conduction velocities, 64%; reduced or absent upper-extremity SNAP amplitudes, 57%; and abnormal lumbar paraspinal needle examination, 22%.⁸⁶ These findings reflect the experience of most clinical electromyographers, and support the electrodiagnostic protocol outlined in Table 45-3. The most severely impaired patients have the greatest number and greatest magnitude of nerve conduction abnormalities.

Summary

Electrodiagnostic studies are a valuable component of the overall evaluation of patients with known or suspected diabetes. Often abnormal in asymptomatic, clinically intact diabetic patients, these

studies are almost invariably abnormal in the presence of clinically evident diabetic neuropathy. A normal electrodiagnostic examination makes the diagnosis of diabetic neuropathy unlikely, even in predominantly small-fiber disease. When properly used, nerve conduction studies and needle electromyography can suggest the underlying pathophysiology, monitor disease progression or improvement, or identify peripheral disorders other than neuropathy that may be causing diagnostic confusion. The use of electrodiagnostic studies in clinical trials is similarly important, although the trials must be sufficiently long to permit physiologic improvement or deterioration.⁸⁷

Standardized Criteria to Diagnose and Monitor Neuropathy for Clinical Trials

A comprehensive set of diagnostic criteria for detection and staging of diabetic neuropathy was first introduced in 1985 by Dyck and colleagues.⁸⁸ In response to widespread interest generated by these criteria and by ongoing clinical treatment trials in diabetic neuropathy, the American Diabetes Association and the American Academy of Neurology convened a panel in 1988. Now known as the San Antonio Consensus Conference on Diabetic Neuropathy, this group recommended a set of research guidelines defining subclinical and clinical diabetic neuropathy.⁸⁹ The panel suggested that each patient have at least one measure from quantitative tests of (1) clinical symptoms, (2) clinical signs, (3) quantitative sensory testing, (4) autonomic function testing, and (5) electrodiagnostic studies. Results from these tests place patients into definable categories.

The diagnosis of subclinical diabetic neuropathy (Table 45-1, class I) requires the demonstration in a diabetic patient of objective measurement of peripheral neural impairment not attributable to a nondiabetic etiology in the absence of detectable clinical signs or symptoms of neuropathy. The diagnosis of clinical diabetic neuropathy (Table 45-1, class II) requires the demonstration in a diabetic patient of symptoms or signs plus objective measurement of peripheral neural impairment not attributable to a nondiabetic etiology. Since there are no distinguishing features unique to diabetic neuropathy, all other likely causes of peripheral neuropathy or disorders that mimic peripheral neuropathy must be excluded by careful history and physical examination and appropriate diagnostic tests (Table 45-4). Neuropathy must also accompany currently accepted diagnostic criteria for diabetes.⁹⁰ Since neuropathic symptoms are often vague and nonspecific, confirmatory clinical signs or objective measurements of peripheral nerve dysfunction (somatic or autonomic) must be present.

OUTPATIENT DIAGNOSIS OF NEUROPATHY

The diagnostic criteria of the San Antonio Conference were developed for research trials and are difficult to employ in routine clinical practice. The Michigan Neuropathy Program is a two-part assessment developed to diagnose and stage diabetic neuropathy in an outpatient setting.³⁴ In part one, a simple 8-point clinical examination, designated the Michigan Neuropathy Screening Instrument (MNSI), is administered by a health care professional (Fig. 45-1). An MNSI score of >2 indicates the presence of neuropathy with a high specificity (95%) and sensitivity (80%).^{86,91} The severity of neuropathy is determined in the second part of the Michigan Neuropathy Program. A focused 146-point neurologic examination is administered by a health care professional (Fig. 45-2), followed by routine nerve conduction studies (sural, peroneal motor, median sensory, and motor and ulnar sensory). The severity of neuropathy

is graded in each patient by a composite score consisting of the number of abnormal nerve conduction and total points from the clinical examination (Fig. 45-3). This program has been successfully used in diabetic outpatient clinics for the screening and simple staging of diabetic neuropathy.⁹

The Semmes-Weinstein 5.07 (10-g) monofilament provides a simple screening tool for diabetic neuropathy and is recommended for this use by the International Diabetes Federation and the World Health Organization European St. Vincent Declaration.⁹²⁻⁹⁵ The

monofilament buckles when a 10-g force is applied.⁹⁶ In some office settings, patients are tested for the ability to sense the monofilament at 10 sites on the foot.^{92,97} Inability to perceive the filament correlates with an insensate foot and diabetic neuropathy.^{92,93} A recent study examined the variation and sensitivity of the 10 different sites and found that examining only 2 sites can provide useful information: these are sites 3 and 4, the plantar aspect of the first and fifth metatarsal heads. If a patient can not feel the monofilament in these locations, there is a high sensitivity and specificity (80% and 86%, respectively) that the patient has diabetic neuropathy.⁹⁸

MANAGEMENT APPROACHES TO THE CLINICAL SYNDROMES OF DIABETIC NEUROPATHY

As summarized earlier, clinically evident diabetic neuropathy is subdivided into a series of distinct but not mutually exclusive clinical syndromes that may occur concurrently in individual patients. The diffuse forms of diabetic neuropathy, distal symmetric sensorimotor polyneuropathy, and autonomic neuropathy are by far the most common syndromes, occurring in a large proportion of neuropathic patients. Distal symmetric sensorimotor polyneuropathy usually starts with sensory findings, affecting the distal sensation in a stocking-glove distribution, with later and less prominent motor involvement usually involving the most distal muscle groups. Autonomic neuropathy generally involves multiple organ systems, but

clinical presentation and symptoms are often centered within a single organ system. Less common are a variety of focal neuropathic syndromes that either involve single nerves or groups of peripheral nerves, including the cranial nerves, or involve other focal regions of the peripheral nervous system.

The diffuse nature and chronic progressive course of distal symmetric polyneuropathy and autonomic neuropathy suggest metabolic neuropathies, whereas the rapid onset, limited distribution, and self-limited nature of the focal neuropathies suggest a vascular basis. Because the neuropathic syndromes of diabetes are indistinguishable from a variety of other forms of peripheral neuropathy, the diagnosis of diabetic neuropathy is a diagnosis of exclusion, requiring appropriate diagnostic work-up for other causes of neuropathy (Table 45-4).

FOCAL NEUROPATHIES

Focal and multifocal diabetic neuropathies with neurologic deficits confined to the distribution of single or multiple peripheral nerves are termed *diabetic mononeuropathy* and *diabetic mononeuropathy multiplex*, respectively. The appearance of neurologic deficits in the distribution of focal lesions at the level of the brachial or lumbosacral plexuses is termed *diabetic plexopathies*, whereas those conforming to deficits at the level of nerve roots are termed *diabetic radiculopathy*. When diabetic mononeuropathy or mononeu-

ropathy multiplex involves cranial nerves, it is then termed *diabetic cranial neuropathy*.

Cranial Neuropathies

Isolated cranial neuropathies occur in diabetic patients, especially the aged (but rarely in diabetic children).⁵⁴ Signs and symptoms of more generalized diabetic neuropathy may be absent, though the cranial palsies may be recurrent or bilateral. As noted above, the

third cranial nerve is most commonly involved, characteristically with pupillary sparing (in contrast to vascular oculomotor compression palsy, where pupillary dilatation is usually an early feature).⁵⁴ Patients classically present with unilateral ophthalmoplegia that spares lateral eye movement, and headache. The accompanying pain is typically intense and referred above or behind the eye, but may be mild or absent in 50% of cases.⁵⁴ The responsible nociceptors are thought to be either perineurial or in the adjacent first and second divisions of the trigeminal nerve, since the third nerve is essentially

purely motor.⁵⁴ Progressive diminution of pain and return of oculomotor function is the rule, even in elderly patients.

The intracavernous portion of the third nerve represents a vascular watershed region between the intra- and extracranial circulation, where vascular supply is most tenuous. Focal fusiform central destructive lesions involving the cavernous sinus portion of the third nerve are reported in autopsied cases of isolated diabetic third-nerve palsy. Central nerve fibers were most heavily damaged and demyelinated, while superficial fibers (thought to innervate the pupil) were relatively spared.⁹⁹ Differential diagnosis would include lesions of the midbrain or posterior orbit, aneurysm of the internal carotid, cavernous sinus lesions, and tumors of the base of the brain.⁵⁴

Other cranial nerves that are less commonly involved in diabetic neuropathy include the sixth, the fourth (usually in combination with other cranial nerves rather than alone), and the seventh cranial nerves, presumably also on a vascular basis.⁵⁴ Other than the third and sixth cranial nerves, there is little evidence to suggest that cranial nerve palsies occur more frequently in diabetic individuals.⁵⁴

Mononeuropathy or Mononeuropathy Multiplex

Isolated peripheral nerve palsies occur more commonly in diabetics, but the causal and coincidental relationships are difficult to differentiate.⁵⁷ However, 40% of unselected patients with clinically overt diffuse diabetic neuropathy have either electrophysiologic or clinical evidence of superimposed focal nerve damage at common entrapment or compression sites (e.g., median nerve at wrist and palm, radial nerve in upper arm, ulnar nerve at elbow, lateral cutaneous nerve of the thigh, and peroneal nerve at fibular head), suggesting that diffuse diabetic neuropathy predisposes to focal nerve damage.⁵⁷ This contention is further supported by evidence that the risk of developing carpal tunnel syndrome is more than doubled in diabetic subjects.¹⁰⁰ Nerves not commonly exposed to compression or entrapment damage occasionally demonstrate focal impairment in patients with diabetes, but this may simply reflect coincidental occurrence of diabetes and compression neuropathy.^{57,100}

Diagnosis of mononeuropathy or mononeuropathy multiplex should be confirmed by electrodiagnostic studies. Other nondiabetic causes of mononeuropathy, mononeuropathy multiplex, or both should be excluded, such as vasculitides, acromegaly, coagulopathies, and hypothyroidism.⁵⁷ Compression and entrapment palsies in diabetic patients respond to standard conservative or surgical management (i.e., protection against additional mechanical trauma or surgical release procedures).^{57,100} Treatment of other mononeuropathies is the same as for nondiabetic mononeuropathy and is essentially supportive. Improved glucose control has been suggested, but there are no controlled data to suggest that it is specifically helpful.^{57,100}

Thoracic Radiculopathy (Intercostal Neuropathy, Truncal Neuropathy)

Diabetic thoracic radiculopathy presents with dermatomal pain and loss of cutaneous sensation. The syndrome may involve multiple dermatomal levels and may be bilateral in some cases.⁵⁶ Hypesthesia or paresthesia usually develops during the course of the disorder. Symptoms frequently are attributed to a compressive lesion such as a herniated nucleus pulposus, but radiographic studies and myelography are negative.^{56,80} When pain is prominent, truncal

radiculopathy is frequently misdiagnosed as an acute intrathoracic or intra-abdominal visceral emergency (e.g., myocardial infarction, cholecystitis, peptic ulcer, or appendicitis), with multiple fruitless diagnostic and/or exploratory surgical procedures performed before the correct diagnosis is recognized.^{56,101} Electrodiagnostic studies of the paraspinal muscles are usually diagnostic.^{56,77} Although generally ascribed to acute infarction of the nerve root, confirmatory histopathologic evidence is lacking.⁵⁶ Signs of diffuse distal symmetric polyneuropathy are often present.^{56,80} Spontaneous resolution of both symptoms and signs is the rule, usually within 6–24 months.⁵⁶

Diabetic Polyradiculopathy

In 1953, Garland and Taverer described a syndrome of pain and proximal limb weakness in diabetics, which was later called asymmetric (motor) proximal neuropathy.⁵⁵ Among diabetic neuropathies, this syndrome, also known as diabetic amyotrophy, is second only to polyneuropathy in frequency.⁵⁵ The pathogenesis of this syndrome is controversial and has been ascribed to lesions of the anterior horn cell, lumbar roots, lumbar plexus, or femoral nerve. Bastrom and Thomas¹⁰² attempted to unify the diverse concepts surrounding diabetic amyotrophy by proposing that the syndrome represented a diabetic polyradiculopathy that preferentially involved the high lumbar roots L2, L3, and L4. A recent study by Dyck and associates suggests that ischemic injury secondary to microscopic vasculitis of lumbosacral roots, plexuses, and nerves underlies the disease process in both diabetic¹⁰³ and nondiabetic patients.¹⁰⁴

In patients with diabetes, the syndrome occurs spontaneously, with pain and sensory impairment and disabling weakness of thigh flexion and knee extension.⁵⁵ Pain classically extends from the hip to the anterior and lateral surface of the thigh. The pain may develop insidiously or episodically, and may be worse at night. Muscle weakness most often involves the iliopsoas, quadriceps, and adductor muscles, but usually spares the hip extensors and hamstrings.⁵⁵ The anterolateral muscles in the calf may also be involved, mimicking an anterior compartment syndrome. Distal symmetric polyneuropathy is almost always present.⁵⁵ Nearly complete recovery is the rule though not universal, and the syndrome may persist for several years or recur.⁵⁵

The syndrome may be distinguished from sciatic neuropathy by a normal straight leg-raising test. Because of the similarities between diabetic polyradiculopathy and that which occurs in association with other conditions, diabetic polyradiculopathy remains a diagnosis of exclusion: space-occupying lesions, trauma, nondiabetic vasculopathies, and skeletal abnormalities must be carefully excluded.⁵⁵ Treatment for high lumbar diabetic polyradiculopathy syndrome is supportive pending spontaneous recovery, although several investigators suggest that treatment with intravenous gamma globulin may speed recovery.¹⁰⁵ The beneficial effect of improved diabetic control, though often commented on, remains unsupported.

POLYNEUROPATHY

Distal symmetric polyneuropathy is generally conceded to be the most widely recognized form of diabetic peripheral neuropathy.^{3,4,10,12,13} The neurologic deficit is classically distributed over all sensorimotor nerves, but demonstrates a distinct predilection for the most distal innervated sites in a more or less symmetrical

fashion.^{46,106,107} Similar distributions are shared by other metabolic neuropathies, including uremic and various nutritional neuropathies.^{80,108} Neurological impairment begins in the most distal portions of the peripheral nervous system, usually the feet or toes, and extends proximally in both the upper and lower extremities. With continued progression, a coexisting vertical anterior chest band of sensory deficit develops as the tips of the shorter truncal nerves become involved (Fig. 45-4).^{106,107,109} As discussed in preceding sections, the diffuseness of peripheral nerve damage in distal symmetric polyneuropathy is evidenced by both electrophysiologic and histologic studies.¹¹⁰ There is generalized motor and sensory conduction slowing and axonal degeneration and demyelination in patients with distal symmetric polyneuropathy, with slowing of nerve conduction closely paralleling histologic fiber loss.^{77,88} Both the histologic and electrophysiologic changes appear earlier and are more pronounced in the most distal components of the peripheral nervous system.¹¹

The signs, symptoms, neurologic deficits, and electrophysiologic characteristics of distal symmetric polyneuropathy vary depending on the classes of nerve fibers that are involved. However, the symptoms and signs always initially appear in a distal distribution and spread proximally, with disease progression in a fiber-length-dependent fashion.^{8,28} Because the signs and symptoms of diabetic distal symmetric polyneuropathy are identical to those that occur in distal symmetric neuropathies of other etiologies (Table 45-4), the clinical diagnosis is one of exclusion.^{20,31,32}

FIGURE 45-4. Sensory deficits in distal symmetric polyneuropathy. (Reprinted with permission from Low PA, Tuck RR, Takeuchi M: *Nerve microenvironment in diabetic neuropathy*. In: *Diabetic Neuropathy*. Dyck PJ, Thomas PK, Asbury AK, Winegrad AJ, Porte D Jr. Eds. Saunders:1987; 266.)

Clinical Signs and Symptoms of Distal Symmetric Polyneuropathy

As stated earlier, the signs and symptoms of distal symmetric polyneuropathy vary considerably depending on the spectrum of nerve fiber involvement. Large sensory fiber loss produces diminished position and light touch sensation, whereas small-fiber damage produces diminished pain and temperature sensation.^{8,20,31,32} Usually both large and small sensory fibers are involved in the neuropathic process to a similar degree, producing a mixed sensorimotor peripheral polyneuropathy. Motor weakness is usually not marked, primarily involving the most distal intrinsic muscles of the hands and feet as a rather late feature. However, diminished deep-tendon reflexes, especially the Achilles tendon reflex, are often an early feature.^{11,68,107,109}

Some patients, with more selective fiber damage, present as variations of this general theme. If large-fiber sensory loss predominates, patients present with impaired balance, diminished proprioception and position sense, and absent or reduced vibration sensation. Subjective symptoms of pain, paresthesia, or numbness are usually absent, and the neuropathy may present only via a late neuropathic complication such as a Charcot's joint or a neuropathic ulceration (see below).^{106-108,111} With severe large-fiber involvement, loss of position sense may result in a sensory ataxia, which is referred to as a "pseudotabetic" form of diabetic neuropathy. In this variant, nerve conduction slowing is usually clearly demonstrable due to the involvement of the large, rapidly conducting fiber population.^{106-108,111} If the neuropathy primarily involves small sensory fibers, then the patient may present with undetected trauma of the extremities (e.g., burns of the fingers from cigarettes, burns of the feet from stepping into hot bath water, or acute abrasions and ulcerations of the feet from small objects retained inside the shoe that go undetected for prolonged periods due to insensitivity to pain). Alternatively, patients with small sensory fiber involvement may present with subjective symptoms of numbness or feelings of "cold feet" or "dead feet."^{11,68,107,109}

Several kinds of spontaneous pain may be associated with small-fiber damage in diabetic neuropathy.⁶⁸ Most commonly, patients experience typical neuropathic distal paresthesias (spontaneously occurring uncomfortable sensations) or dysesthesias (contact paresthesias).¹¹² Some patients complain of exquisite cutaneous contact hypersensitivity to light touch. At times the pain is described as superficial and burning, shooting or stabbing, or bone-deep and aching or tearing.¹¹³ Often the pains are more pronounced at night, producing insomnia.¹¹⁴ At times, pain can become an overriding and disabling feature of diabetic neuropathy. Muscle cramps, which begin distally and slowly ascend, are similar to those reported in other muscle denervation disorders. Because disease involvement in these patients may be primarily confined to the small myelinated nerve fibers, conduction velocity may not be dramatically impaired, vibration sensation may be intact, motor weakness may be absent, and, if the patient's symptoms bring him or her to the physician's attention early in the course of the disease, sensory loss may not be striking.¹¹⁵ The presence of painful symptoms in the absence of striking neurologic deficit appears somewhat paradoxical; however, painfulness may reflect increased fiber regeneration, which may commence before degeneration is sufficiently severe to present marked sensory deficit.^{112,115}

Most patients with diabetic neuropathy experience either no or only slight subjective symptoms and present to the physician with asymptomatic neurologic deficits detected on physical examina-

tion, or with complications resulting from the asymptomatic sensory deficits.^{11,116} Pure or primarily motor neuropathy is very rare in diabetes, and its presence suggests an alternate etiology such as Guillain-Barré syndrome.¹⁰⁸ A primary motor neuropathy has been associated with insulin-induced hypoglycemia in psychiatric patients and in insulinoma; animal experiments support the concept of a hypoglycemic peripheral neuropathy.¹¹⁷ Hence recurrent iatrogenic hypoglycemia should be considered in any diabetic presenting with a primarily motor distal neuropathy.¹¹⁷

Complications of Distal Symmetric Polyneuropathy

The mechanical and traumatic consequences of distal symmetric polyneuropathy are largely preventable, and as such represent a failure of medical management when they occur.²¹ Moreover, they constitute a significant risk to the neuropathic patient.¹¹⁸ Their prophylaxis is a major target of standard diabetes patient education, especially that dealing with foot care and hygiene.^{72,119}

Neuropathic Foot Ulceration

Traumatic damage to the skin and soft tissues of the foot occurs with great frequency in most sensory neuropathies, including diabetic distal symmetric polyneuropathy.²² Central to all forms of diabetic foot ulceration is insensitivity to pain, although diminished proprioception and muscle strength as well as vascular factors may play contributing roles.²² In the classic plantar ulcer, neurogenic atrophy of the intrinsic foot muscles, which normally tonically counterbalance the more proximal foot flexors and extensors, results in chronic flexion of the metatarsal-phalangeal joints,

thereby drawing the toes into a curled-up position (claw toe deformity). Weight bearing is then shifted to the now uncovered metatarsal heads, leading to thinning and atrophy of the normal fat pad. In the absence of pain, thick calluses form over the exposed metatarsal bony prominences and protrude from the plantar surface of the foot, further shifting weight bearing to the metatarsal heads (Fig. 45-5).^{120,121} The calluses first thicken and then undergo liquefaction. The dry overlying skin breaks down, possibly reflecting in part the diminished lubrication secondary to decreased sudomotor activity of the generally accompanying autonomic neuropathy.¹²⁰⁻¹²² The resulting central ulcerations may remain unnoticed in the absence of pain sensation, even when secondary infection develops.^{22,123} Plantar ulcers, which develop when abnormal foot architecture transfers body weight onto normally non-weight-bearing areas of the foot, are usually located at callused sites of maximal walking pressure. With further architectural deformity due to neuroarthropathy or amputation, plantar ulcers may develop at alternative weight-bearing sites.¹²⁴⁻¹²⁶

Neuropathic foot ulcers also develop at other locations through other mechanisms in the absence of callus formation. The deformed neuropathic foot does not conform well to the shape of the standard shoe, leading to pressure lesions and/or abrasions at locations other than weight-bearing sites.^{22,121} The generally thin dorsal dermis of the foot may be abraded within hours, so that repeated self-examinations are mandatory when new footwear is worn or with prolonged walking or weight bearing in the absence of pain sensation.^{21,22}

Ischemia has been invoked as a factor in diabetic foot ulceration, but its role is controversial. Toe blood pressures have been found to be reduced in patients with neuropathic foot ulceration,

FIGURE 45-5. The pathogenesis of diabetic foot ulcers. (Reprinted with permission from Kwasnik E: Surg Clin North Am 1986;66:305.)

even when the ankle:brachial pressure is normal.^{127,128} However, the role of vessel disease of the toes in foot ulceration remains unclear. Frank ischemic gangrene may be hastened in neuropathic feet since ischemic rest pain may go unnoticed.^{127,128} Proximal atherosclerotic vascular insufficiency undoubtedly delays healing of neuropathic foot ulcers.¹²⁸ However, the neuropathic ulcerated foot is characteristically warm, with easily palpable pulses, mitigating against an important large-vessel ischemic component.¹²⁷⁻¹²⁹ Doppler flow studies confirm that blood flow to the neuropathic foot is generally increased, and suggest that this increased flow results from abnormal local arteriovenous shunting.^{127,128} The role of increased arteriovenous shunting in the pathogenesis of both complications of the diabetic foot, and recently in the development of peripheral neuropathy itself, remains speculative. Increased AV shunting in the foot with diabetic neuropathy is thought to reflect loss of the tonic sympathetic vascular innervation, and there has been debate whether this shunting may precipitate a skin-nutritive capillary steal phenomenon that leads to poor ulcer healing.^{127,128} There is little evidence to support such a steal phenomenon, because capillaries are normal in number and patent in diabetic subjects with advanced neuropathy.^{127,128} Likewise, an increase in the number of arteriovenous shunts has been directly observed in human sural nerve, but their functional significance in the development of endoneurial ischemia is unclear.¹²⁷⁻¹²⁹

Prophylactic treatment of diabetic foot ulcers is accomplished through reinforcement of foot care education in patients with distal symmetric polyneuropathy, identification of abnormal weight bearing and/or callus formation before ulceration occurs, and prescription of appropriate behavioral and mechanical measures to reduce weight bearing.^{21,118,130} This would include weight reduction, decreased weight-bearing activity, the use of a cane or cushioned shoes, and specific orthotic devices and inserts to distribute necessary weight bearing in a less threatening fashion.^{21,118,130} Once ulcers have occurred, the treatment of diabetic foot ulcers is removal of the traumatic elements that contributed to the ulcer formation.¹³¹ Readjustment of weight bearing with appropriate orthopedic devices is essential. In some cases, partial or complete elimination of weight bearing is required through decreased ambulation, support with a cane or crutches, use of a wheelchair, or enforced bed rest.¹³⁰⁻¹³² When callus protrusions further disturb weight bearing, then appropriate debridement, trimming, and abrasion are indicated.¹³¹ The application of a walking cast that transfers weight bearing to the upper leg is sometimes helpful; however, the cast must be removed and the leg examined for abrasions or ulcerations at the site to which weight bearing has been shifted.¹³² Complicating infection should be treated with antibiotics, including a drug directed against anaerobic bacteria that may be difficult to culture from an open wound.¹²³ In refractory cases, removal of the offending metatarsal head, sometimes together with amputation of the toe, may be necessary (see Chap. 51).¹³³

Neuroarthropathy (Charcot's Joint)

Neuroarthropathy can occur in any nervous system disease that leaves motor function relatively intact but impairs sensation. The primacy of nociceptive impairment in the pathogenesis of neuroarthropathy is supported by its reported occurrence in the "congenital indifference to pain syndrome," where motor and proprioceptive function remain intact. The nociceptive impairment also explains the almost complete absence of pain in many cases of diabetic neuroarthropathy.^{134,135} Tabetic neuroarthropathy classically involves the large weight-bearing joints, while diabetic neuroarthropathy

primarily involves distal joints of the foot (tarsal-metatarsal or metatarsal-phalangeal) or the ankle.¹³⁴ The presentation of recent-onset diabetic neuroarthropathy is usually one of painless swelling and redness of the foot in the absence of fever or leukocytosis, but in the presence of clearly demonstrable distal symmetric sensory deficit and evidence of peripheral autonomic nerve failure.⁴⁸ The differential diagnosis is usually cellulitis or osteomyelitis, depending on the extent of radiographic bony destruction.¹³⁵

Unhealed painless fractures are often evident radiographically, and a recent history of painless trauma is frequently but not always elicited. In later stages, the disorder presents as gross architectural distortion of the foot, with shortening and widening of the joint. In its most advanced stage, there are multiple painless fractures accompanied by extensive bone demineralization and reabsorption, so that the foot appears to the examiner as "a bag of bones."^{48,134} As with other forms of neuroarthropathy, the pathogenetic mechanism is presumed to be multiple recurrent traumatic insults to the joint and surrounding bony structures that are not noticed by the patient because of insensitivity to pain.¹²⁷ Increased bone blood flow due to arteriovenous shunting may also serve to weaken the bone, predisposing the foot to fractures.¹²⁷ Prophylactic measures include reinforced education in patients with diminished pain and proprioceptive sensation, especially the avoidance of prolonged weight bearing, the wearing of cushioned shoes, avoidance of strenuous weight-bearing exercise or athletic activities, and ambulating only over well-lighted smooth terrain in well-fitting footwear.^{21,130} Therapy is directed at removal of continued trauma by removing the involved extremity from weight bearing, either by decreasing ambulation or by providing other means of weight bearing, for example, a cane, crutches, or a wheelchair.^{48,131,132}

Treatment of Neuropathy

Initial treatment strategies in diabetic neuropathy consist of optimal glucose control and foot care. Before the DCCT, the scientific rationale for these therapeutic strategies was based on studies in animal models of diabetes and epidemiologic reports. The DCCT provided direct evidence that optimal glucose control in insulin-dependent diabetic patients can decrease neuropathy frequency, with a reported 60% reduction in the incidence of clinical neuropathy in the combined primary- and secondary-prevention cohorts.¹³⁶ Similar results are reported in the Stockholm Diabetes Intervention Study, where intensive insulin treatment of diabetic patients preserved nerve conduction velocities when compared to conventional treatment.^{58,59} Optimal glucose control must occur in the setting of rigorous foot care. On a nightly basis, patients are required to carefully inspect their feet for the presence of dry or cracking skin, fissures, plantar callus formation, and signs of early infection in between the toes and the toenails.

A stepwise, systematic treatment plan constitutes the best approach to a patient with painful diabetic neuropathy¹³¹ and has recently been reviewed in detail.¹³⁷ Categorization of painful symptoms by duration and potential precipitating causes provides helpful prognostic indicators. Patients with symptoms of less than 6 months' duration associated with alterations in glycemic control have a good prognosis when compared to patients with chronic symptoms lasting longer than 6 months.^{26,131} Table 45-5 lists currently available drugs reported to have therapeutic benefits in the treatment of diabetic neuropathy. Nonsteroidal anti-inflammatory drugs can offer pain relief, especially in patients with musculoskeletal or joint abnormalities secondary to long-standing neu-

TABLE 45-5. Drugs Used in the Treatment of Painful Diabetic Neuropathy

1. Nonsteroidal Drugs
Ibuprofen 600 mg four times a day
Sulindac 200 mg twice a day
2. Antidepressant Drugs
Amitriptyline 50–150 mg at night
Nortriptyline 50–150 mg at night
Imipramine 100 mg daily
Paroxetine 40 mg daily
Trazadone 50–150 mg three times a day
3. Antiepileptic Drugs
Gabapentin 600–1200 mg three times a day
Carbamazepine 200 mg four times a day
4. Others
Tramadol 50–100 mg twice a day
Mexiletine 150–450 mg daily
Capsaicin 0.075% four times a day
Transcutaneous electrical nerve stimulation (TENS)

ropathy. In this group of patients, joint deformities may actually be the primary source of pain. A double-blind placebo-controlled fixed-dose study revealed that both ibuprofen (600 mg four times daily) and sulindac (200 mg twice daily) brought substantial pain relief in patients with diabetic neuropathy.¹³⁸

The tricyclic antidepressants are the most commonly used drugs in the treatment of painful neuropathy. They act by blocking the re-uptake of norepinephrine and serotonin, potentiating the inhibitory effect of these neurotransmitters on nociceptive pathways.¹³⁹ Double-blind, placebo-controlled trials have reported that both amitriptyline^{140,141} and imipramine^{142,143} relieve neuropathic pain. After 6 weeks of amitriptyline treatment, patients report significant pain relief, independent of mood but correlating with increasing drug dosage.¹⁴⁴ The side effects of amitriptyline, secondary to its strong anticholinergic properties, include sedation, urinary retention, orthostatic hypotension, and cardiac arrhythmias. If side effects become intolerable, nortriptyline, which is less sedating, can be substituted for amitriptyline.¹⁴⁵ Urinary retention may occur with either amitriptyline or nortriptyline, mandating a change to imipramine therapy. Two double-blind crossover studies have independently reported that imipramine improves neuropathic pain and nocturnal exacerbation of symptoms.^{142,143} Additional support for the use of tricyclics for the treatment of neuropathic pain is provided by a recent meta-analysis of 21 trials.¹⁴⁶ In patients with a significant cardiac history, amitriptyline or nortriptyline is contraindicated and therapeutic regimens include either doxepin, the least cardiotoxic tricyclic antidepressant, or desipramine. The topical cream capsaicin can be added to the patient's therapeutic regimen if neuropathic pain persists in spite of treatment with maximally tolerated doses of antidepressant medication.¹⁴⁵ In an outpatient setting, approximately two-thirds of diabetic patients treated with a combination of antidepressant medication and capsaicin cream experience substantial relief of neuropathic pain.

Serotonin reuptake inhibitors may also alleviate neuropathic pain, but the evidence for this is less convincing than that for tricyclic antidepressants. In a randomized, double-blind, crossover study, paroxetine 40 mg per day reduced neuropathic symptoms compared to placebo.¹⁴⁷ Fluoxetine (40 mg per day) was no more effective than placebo except in diabetic patients with depression superimposed on neuropathy in a double-blind, placebo-controlled

study.¹⁴⁸ Open-label sertraline and trazodone are often used empirically, suggesting the possibility that these drugs may have some efficacy in treating painful diabetic neuropathy, but there are no controlled studies.^{149,150}

The anticonvulsant gabapentin has recently emerged as the therapy of choice for many clinicians.¹⁵¹ Gabapentin is more effective than placebo when used in doses ranging from 900–3600 mg per day,¹⁵² although the lower end of this dosage range (900 mg) may be relatively ineffective.¹⁵³ Side effects of gabapentin therapy include dizziness, somnolence, headache, diarrhea, confusion, and nausea. A randomized double-blind study comparing the efficacy of gabapentin with amitriptyline found that both drugs provided equal pain relief with no difference between mean pain score and global pain score.¹⁵⁴

In patients who experience continued pain on combination therapy (i.e., a tricyclic or gabapentin with capsaicin), carbamazepine can be considered and added as a third drug.^{155,156} Dizziness, nausea, and a truncal skin rash are the common side effects of this drug, although reports of leukopenia mandate that a patient have a complete blood count with differential weekly for the first month, and monthly for the next 3 months upon beginning carbamazepine therapy.¹⁵⁷ Phenytoin has been used as an alternative to carbamazepine,¹⁵⁸ although a double-blind, crossover study reported that phenytoin provides no significant relief of neuropathic pain in patients with diabetic neuropathy.¹⁵⁹ In patients who experience continued pain on antidepressant medication or gabapentin, capsaicin cream, and carbamazepine, the carbamazepine can be discontinued and a different third drug added to the therapeutic regimen. Choices include oral mexiletine or intravenous lidocaine, both of which are reported to improve neuropathic pain,^{160,161} but use of these agents requires clearance from a cardiologist and, in the case of lidocaine, an inpatient hospitalization with cardiac monitoring. Levodopa, gamma-linolenic acid, and dextromethorphan also have reported efficacy.¹³⁷ If neuropathic pain persists despite the outlined treatment regimen, addition of a transcutaneous electrical nerve stimulation (TENS) unit, acupuncture, or a series of local nerve blocks may be helpful, although the prognosis for pain relief in these patients is poor.

Diabetic Autonomic Neuropathy

Aaron I. Vinik

Tomris Erbas

Michael A. Pfeifer

Eva L. Feldman

Martin J. Stevens

James W. Russell

Diabetic neuropathy is the most common and troublesome complication of diabetes mellitus, leading to great morbidity and mortality and an increase in the economic burden of public health.¹ Diabetic neuropathy is a heterogeneous disorder that encompasses a wide range of abnormalities affecting both proximal and distal, peripheral sensory and motor, and autonomic nervous systems (ANS). The ANS supplies all organs in the body and consists of an afferent and an efferent system, with long efferents in the vagus (cholinergic) and short postganglionic unmyelinated fibers in the sympathetic system (adrenergic). A third component is the neuropeptidergic system, with its neurotransmitters substance P (SP), vasoactive intestinal polypeptide (VIP), calcitonin gene-related peptide (CGRP), and others.

Diabetic autonomic neuropathy (DAN) can cause dysfunction of every part of the body. "Know DAN and you know the whole of medicine." DAN often goes completely unrecognized by patient and physician alike because of its insidious onset and protean multiple organ involvement. Alternatively, the appearance of complex and confusing symptoms in a single organ system due to DAN may cause profound symptoms and receive intense diagnostic and therapeutic attention. Subclinical involvement may be widespread, whereas clinical symptoms and signs may be focused within a single organ. Tests of autonomic function generally stimulate entire reflex pathways. Furthermore, autonomic control for each organ system is usually divided between opposing sympathetic and parasympathetic innervation, so that heart rate acceleration, for example, may reflect either decreased parasympathetic or increased sympathetic nervous system stimulation. The organ systems that most often exhibit prominent clinical autonomic signs and symptoms in diabetes include the ocular pupil, sweat glands, genitourinary system, gastrointestinal tract system, adrenal medullary system, and cardiovascular system (Table 46-1).

ANS disturbances may be functional, e.g., gastroparesis with hyperglycemia and ketoacidosis, or organic, in which nerve fibers are actually lost. This creates inordinate difficulties in diagnosing, treating and prognosticating as well as establishing true prevalence rates.

TABLE 46-1. Clinical manifestations and differential diagnosis of autonomic neuropathy

Clinical Manifestations	Differential Diagnosis
Cardiovascular	Cardiovascular disorders
Tachycardia, exercise intolerance	Idiopathic orthostatic hypotension
Cardiac denervation	Shy-Drager syndrome
Orthostatic hypotension	Panhypopituitarism
	Pheochromocytoma
	Hypovolemia
	Congestive heart disease
	Carcinoid syndrome
Gastrointestinal	Gastrointestinal disorders
Esophageal dysfunction	Obstruction
Gastroparesis diabeticorum	Bezoars
Diarrhea	Secretory diarrhea (endocrine tumors)
Constipation	Biliary disease
Fecal incontinence	Psychogenic vomiting
	Medications
Genitourinary	Genitourinary
Erectile dysfunction	Genital and pelvic surgery
Retrograde ejaculation	Atherosclerotic vascular disease
Cystopathy	Medications
Neurogenic bladder	Alcohol abuse
Neurovascular	Other causes of neurovascular dysfunction
Heat intolerance	Chagas disease
Gustatory sweating	Amyloidosis
Dry skin	Arsenic
Impaired skin blood flow	
Metabolic	
Hypoglycemia unawareness	
Hypoglycemia unresponsiveness	
Hypoglycemia associated autonomic failure	
Pupillary	Pupillary
Decreased diameter of dark adapted pupil	Syphilis
Argyll-Robertson type pupil	

PREVALENCE

The main subgroups of autonomic disturbances recognized in diabetes mellitus are (1) subclinical DAN, determined by abnormalities in quantitative autonomic function tests; and (2) clinical DAN, which presents with symptoms or signs. There are few studies on the prevalence of the two types. The reported prevalence of DAN varies, depending on whether the studies have been carried out in the community, clinic, or a tertiary referral center. This variance also reflects the type and number of tests performed and the presence or absence of signs and symptoms of autonomic neuropathy. Most patients who develop signs of DAN do not become symptomatic. Symptomatic autonomic neuropathy is rare and presents in less than 5% of diabetic patients, except for impotence (5–50%). Clinical symptoms of DAN generally do not occur until long after the onset of diabetes. However, subclinical autonomic dysfunction can occur within a year of diagnosis in type 2 diabetic (T2DM) patients and within 2 years in type 1 diabetic (T1DM) patients.²

In the population-based Oxford Community Diabetes Study, 20.9% of T1DM and 15.8% of T2DM individuals had abnormal results in one or more of three autonomic function tests.³ In a clinic-based study, cardiac autonomic neuropathy was present in 8–22% of T1DM and T2DM patients on screening.⁴ The prevalence of autonomic neuropathy was 47% in the EURODIAB IDDM Complications Study.⁵

The major confirmed risk factors are age, duration of diabetes, poor metabolic control, and the presence of retinopathy, nephropathy, and cardiovascular disease. Autonomic neuropathy also involves severe hypoglycemia and severe ketoacidosis.^{5,6}

Complications affecting the autonomic nervous system contribute greatly to the morbidity, mortality, reduced quality of life, and activities of daily living of the person with diabetes. They are also major sources of increased cost of caring for the diabetic patient. Among the most troublesome and dangerous of these conditions that are linked to autonomic neuropathy are (1) myocardial ischemia including silent myocardial infarction; (2) cardiac arrhythmias; (3) foot ulceration, gangrene, and amputation; (4) nephropathy; and (5) erectile dysfunction. Parasympathetic nerve dysfunction in T2DM patients is associated with features of the metabolic insulin resistance syndrome, a common risk factor for cardiovascular morbidity and mortality. Patients with parasympathetic neuropathy have elevated fasting C-peptide and triglyceride levels and lowered high-density lipoprotein (HDL) cholesterol levels.⁷ Basal hyperinsulinemia is associated with the development of parasympathetic autonomic neuropathy in T2DM. Basal proinsulin and C peptide are also associated with autonomic nerve dysfunction.⁸

The presence of symptomatic autonomic dysfunction is life-threatening, with estimates of mortality ranging from 25 to 50% within 5–10 years of diagnosis; mortality estimates on meta-analysis of nine studies averaged 27% in 2–5 years.^{9–13} The 5-year mortality rate of patients with DAN is three times higher than that in diabetic patients without autonomic involvement.¹⁴

PATHOGENESIS

The pathogenesis of autonomic neuropathy is incompletely understood. There are metabolic, microvascular, and autoimmune theories (see Chap. 44). Persistent hyperglycemia resulting in activation of the polyol pathway and tissue accumulation of sorbitol,

fructose, and deficiency of myoinositol, disturbed phosphoinositide metabolism with consequent decreased nerve Na^+/K^+ -ATPase activity, increased nonenzymatic glycation, decreased nitric oxide (NO) production leading to impaired endothelium-dependent vasodilation, and finally deficiency in neurotrophic factors have all been proposed as pathogenetic mechanisms for DAN.^{15,16}

Although there is increasing evidence that the pathogenesis of DAN involves several mechanisms, the prevailing theory implicates persistent hyperglycemia as the primary factor within the metabolic hypothesis.¹⁷ Persistent hyperglycemia increases polyol pathway activity, with accumulation of sorbitol and fructose in nerves, damaging them by an as yet unknown mechanism. This is accompanied by decreased myoinositol uptake and inhibition of the Na^+/K^+ -ATPase, resulting in Na^+ retention, edema, axoglial disjunction, and nerve degeneration. Microvascular dysfunction with local ischemia leading to nerve fiber death has been proposed, as well as pseudohypoxia with oxidative stress.^{18,19} An immunologic mechanism has also been suggested in the etiology of DAN. Autoantibodies to vagus nerve, sympathetic ganglia, and adrenal medulla are higher in patients with severe symptomatic DAN. Complement-fixing autoantibodies to the vagus nerve, sympathetic ganglion, and adrenal medulla are present in 13.2–30.7% of patients with T1DM.²⁰ These autoantibodies have been shown to cause apoptosis of adrenergic neurons in culture.^{21–23} Antibodies to nerve growth factor (NGF) (important for viability of sympathetic and neuropeptidergic integrity) have been reported in patients with iritis and gastroparesis.²⁴

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of DAN depends on the systems involved but generally includes idiopathic orthostatic hypotension, Shy-Drager syndrome, multiple system atrophy, panhypopituitarism, pheochromocytoma, carcinoid syndrome, neuroendocrine tumors, hypovolemia, medications (insulin, vasodilators, and sympathetic blockers), orthostatic hypotension caused by alcoholic neuropathy, congestive heart failure, Chagas' disease in Latin America, the familial forms of amyloidosis in people of Mediterranean origin, and the Argyll-Robertson pupil of syphilis. Specific organ involvement requires consideration of causes within each organ system (Table 46-1).

CARDIOVASCULAR AUTONOMIC NEUROPATHY

Cardiovascular autonomic neuropathy (CAN) is a common form of autonomic neuropathy, embracing abnormalities in heart rate control, and central and peripheral vascular dynamics.^{25–28} Parasympathetic activation slows the heart rate, whereas sympathetic activation is both inotropic and chronotropic. Sympathetic stimulation of the vasculature tree increases blood pressure, whereas parasympathetic control of the vasculature has only minor effects. Thus, early parasympathetic damage results in resting tachycardia and with the advent of sympathetic damage heart rate slows but not back to normal. Orthostasis may develop and impaired ventricular function occurs.

The prevalence rate of borderline or definite CAN is 8.5 or 16.8% among T1DM patients and 12.2 or 22.1% in T2DM patients attending a general clinic.⁴ In the Diabetes Control and Complications Trial (DCCT) cohort of young T1DM patients free of compli-

cations, the baseline prevalences of abnormal cardiovascular tests (RR variation and Valsalva ratio) were 1.6% and 6.2%, respectively in the primary prevention cohort, and 6.3% and 5.5%, respectively in the secondary intervention cohort.^{29,30} Surveys of clinical endocrine/diabetes practices that include patients with long-standing diabetes have found >40% abnormalities in heart rate variability (HRV).³¹ Thus, the prevalence varies with the measurements, the device used and the population being studied.

CAN has been linked to postural hypotension, exercise intolerance, enhanced intraoperative cardiovascular lability, increased incidence of silent ischemia, myocardial infarction, and decreased rate of survival after myocardial infarction.³²⁻³⁵ CAN cosegregates with impaired vibration perception and higher urinary albumin excretion in T1DM patients. However, in T2DM patients, it is associated with higher body mass index, systolic blood pressure, urinary albumin excretion, and basal insulin levels, i.e., all features of the metabolic syndrome.³

Cardiac sympathetic denervation is greater in T2DM than in T1DM patients.³⁶ In both normal subjects and diabetic patients, reduced autonomic function, measured as loss of HRV, is associated with a high risk of future coronary heart disease predicted either from conventional coronary risk factors or from exercise test parameters.³⁷ There are links among DAN, higher nocturnal blood pressure levels, increased left ventricular mass, and higher cardiovascular mortality rate. The medical consequences of CAN in diabetes are dramatic: a meta-analysis of 11 studies of CAN among diabetic patients concluded that whereas patients with diabetes without this complication have a mortality of 5% within 5.5 years, mortality among patients with CAN (as determined by abnormal HRV tests) jumps to 27% in that time period.³⁸ Cardiovascular mortality is increased in diabetic patients with autonomic neuropathy independent of conventional risk factors and glycemia.³⁹ Autonomic neuropathy is also an independent risk factor for stroke in T2DM patients.⁴⁰

Cardiovascular Symptoms and Signs

In early CAN there is resting tachycardia and loss of beat-to-beat variation in heart rate with deep breathing.⁴¹ A fixed heart rate unresponsive to mild exercise in diabetic patients indicates nearly complete cardiac denervation. Autonomic neuropathy most commonly involves the cardiovascular system, leading to a reduced cardiac ejection fraction and systolic dysfunction, as well as decreased diastolic filling.^{26,42} The presence of both asymptomatic and symptomatic coronary artery disease (CAD) is increased in diabetic patients, and subclinical neuropathy is an important cause of silent ischemia in patients with diabetes.^{43,44} Indeed, painless ischemia is significantly more frequent in patients with, than in those without, autonomic neuropathy (38% vs. 5%). Diabetic autonomic dysfunction affecting cardiac efferent sympathetic signals is an important determinant of impaired coronary blood flow during increased sympathetic stimulation. Diabetic patients with evidence of cardiac sympathetic nerve dysfunction have impaired sympathetically mediated dilation of coronary resistance vessels. This vasomotor abnormality develops early in the course of DAN, and its severity is related to the degree of cardiac sympathetic nerve dysfunction.⁴⁵

In nondiabetic patients, acute myocardial infarction has a circadian variation, with a significant morning peak. The characteristic diurnal variation in the onset of myocardial infarction is altered in diabetic patients, demonstrating a lower morning peak and a

higher percentage of infarction during evening hours. The blunted morning surge of incidence of myocardial infarction results from altered sympathovagal balance in patients with CAN.^{46,47} Chest pain in any location in a patient with diabetes should be considered of myocardial origin until proved otherwise. Moreover, unexplained fatigue, confusion, tiredness, edema, hemoptysis, nausea and vomiting, diaphoresis, arrhythmias, cough, or dyspnea should alert one to a possible silent myocardial infarct.

Prolongation of the QT interval has been suggested as a diagnostic test of DAN and as a prognostic marker of cardiovascular disease.¹² The EURODIAB Type 1 Diabetes Complications Study found that the prevalence of abnormally prolonged corrected QT is 16% in the diabetic population as a whole, 11% in males and 21% in females.⁴⁸ Prolonged QTc interval and QT dispersion (the difference between the longest and shortest QT interval) are indicative of an imbalance between right and left sympathetic innervation. Diabetic patients with regional sympathetic imbalance and QTc interval prolongation also may be at greater risk for arrhythmias. Prolonged QT intervals indicate an increased risk of sudden death from autonomic neuropathy, diabetic nephropathy, and coronary heart disease.^{49,50}

Regional myocardial autonomic denervation and altered vascular responsiveness in DAN may predispose to malignant arrhythmogenesis and sudden cardiac death. In the resting state, the myocardium is well perfused in subjects with DAN, and thus circulatory deficiencies should not exacerbate arrhythmogenesis under resting conditions. During stress, relative regional ischemia in sympathetically innervated regions with diminished parasympathetic protection may be highly arrhythmogenic.^{51,52} In diabetes, excess cardiac death is related to sympathetic hyperactivity or imbalance because these patients experience proportionally greater cardioprotection from beta blockade, with mortality after infarction being decreased by $\leq 63\%$.^{53,54}

Cardiac Function Testing of the Autonomic Nervous System

The ANS is usually tested by evaluating reflex arcs that involve a stimulus, a receptor, an afferent nerve, central processing, an efferent nerve and an end-organ response.⁵⁵ The ideal test must be simple, specific, noninvasive, and easy to perform and undergo, be sensitive, yield reproducible results, suitable for long-term evaluation. The San Antonio Conference concluded that noninvasive tests of ANS function are suitable for routine screening for autonomic dysfunction or for monitoring the progress of autonomic neuropathy.⁵⁶ A series of simple noninvasive tests is capable of detecting CAN: resting heart rate, beat-to-beat HRV, Valsalva maneuver, heart rate response to standing, systolic blood pressure response to standing, diastolic blood pressure rise with sustained exercise, and QT interval on ECG (Table 46-2). Reduced 24-hour HRV, a newer measure of cardiac autonomic function, is believed to be a more sensitive measure of cardiac autonomic function that is able to detect dysfunction earlier than standard reflex tests.⁵⁷ The abnormal HRV test alone may be useful in diagnosing early-stage autonomic dysfunction. However, with better control of all the variables, an abnormal Valsalva response is more sensitive and reproducible.³¹ Combining these with the standing test 30:15 ratio provides greater sensitivity and reveals a higher number of abnormalities.

Absent HRV secondary to DAN is predictive of both left ventricular failure and increased mortality.⁵⁸ Thus, due to the large percentage of diabetic patients with CAN complications, HRV

TABLE 46-2. Diagnostic tests of cardiovascular autonomic neuropathy

TEST	METHOD/PARAMETERS
Resting heart rate	>100 beats/min is abnormal.
Beat-to-beat heart rate Variation*	With the patient at rest and supine (no overnight coffee or hypoglycemic episodes), breathing 6 breaths/min, heart rate monitored by EKG or ANSCORE device, a difference in heart rate of >15 beats/min is normal and <10 beats/min is abnormal, R-R inspiration/R-R expiration >1.17. All indices of HRV are age-dependent**.
Heart rate response to Standing*	During continuous EKG monitoring, the R-R interval is measured at beats 15 and 30 after standing. Normally, a tachycardia is followed by reflex bradycardia. The 30:15 ratio is normally >1.03.
Heart rate response to Valsalva maneuver*	The subject forcibly exhales into the mouthpiece of a manometer to 40 mmHg for 15 s during EKG monitoring. Healthy subjects develop tachycardia and peripheral vasoconstriction during strain and an overshoot bradycardia and rise in blood pressure with release. The ratio of longest R-R shortest R-R should be >1.2.
Systolic blood pressure response to standing	Systolic blood pressure is measured in the supine subject. The patient stands and the systolic blood pressure is measured after 2 min. Normal response is a fall of <10 mmHg, borderline is a fall of 10-29 mmHg, and abnormal is a fall of >30 mmHg with symptoms.
Diastolic blood pressure response to isometric exercise	The subject squeezes a handgrip dynamometer to establish a maximum. Grip is then squeezed at 30% maximum for 5 min. The normal response for diastolic blood pressure is a rise of >16 mmHg in the other arm.
EKG QT/QTc intervals	The QTc should be <440 ms.
Spectral analysis	- VLF peak ↓ (sympathetic dysfunction) - LF peak ↓ (sympathetic dysfunction) - HF peak ↓ (parasympathetic dysfunction) - LH/HF ratio ↓ (sympathetic imbalance)
Neurovascular flow	Using noninvasive laser Doppler measures of peripheral sympathetic responses to nociception.

* These can now be performed quickly (<15 min) in the practitioners office, with a central reference laboratory providing quality control and normative values. (ANSORE) Boston Medical Technologies.

testing is a very powerful and useful tool for identifying patients at substantial risk of morbidity and mortality. It is also a sensitive, although not specific, indicator of painless myocardial ischemia. In summary, measuring HRV appears to be an effective means of identifying patients at risk for asymptomatic ischemia and infarction so that treatment may be instituted before a cardiac event occurs.

A 24-hour recording of HRV gives insights into abnormal patterns of circadian rhythms regulated by sympathovagal activity. In frequency domain analysis, very low-frequency (VLF) heart rate fluctuations are thought to be mediated by the sympathetic system; the low-frequency (LF) heart rate fluctuations are under sympathetic control with vagal modulation; and the high-frequency (HF) fluctuations are under parasympathetic control. The balance between the sympathetic and parasympathetic components of autonomic nerve function can be assessed with the LF:HF ratio. The HF component is reduced in diabetic patients with vagal dysfunction. In diabetic patients with sympathetic dysfunction, the VLF and LF components are reduced. The VLF, LF, and HF components, as well as the LF:HF ratio, have been demonstrated to be reduced in diabetic patients with advanced stages of CAN.³⁸

Sympathetic innervation of the heart can be visualized and quantified by single-photon emission computed tomography (SPECT) with ¹²³I meta-iodobenzylguanidine (MIBG). MIBG is an analog of norepinephrine that shares the same uptake and storage mechanism. MIBG imaging is a valuable tool for the detection of early alterations in myocardial sympathetic innervation in diabetic patients. Diabetic CAN has been directly characterized by reduced or absent myocardial MIBG uptake.^{59,60} The regional cardiac sympathetic dysinnervation is mainly in the posterior myocardial region compared with the lateral and apical region, implying a predisposition to arrhythmogenicity.⁶¹ Furthermore, alter-

ations of the sympathetic myocardial innervation are related to subclinical left ventricular dysfunction observed in a large proportion of patients with long-standing T1DM.⁶² The sympathetic innervation of the heart can also be visualized with positron emission (PET) imaging using carbon-11 hydroxyephedrine. Defects in carbon-11 hydroxyephedrine uptake have been correlated with CAN and impaired vasodilator response of coronary resistance vessels.^{45,63}

Treatment

The DCCT group has shown without question the importance of attention to intensive insulin therapy in preventing the onset and progression of diabetic complications. The DCCT demonstrated that DAN was reduced by 53% in patients with intensive glycemic control. Intensive therapy caused a significant risk reduction in autonomic nerve abnormalities (4 vs. 9%) in the Primary Prevention Group.²⁹ Furthermore, Burger and colleague⁶⁴ showed the effect of strict glycemic control on HRV in T1DM patients with CAN. The response to improved glycemic control is dependent on the degree of autonomic dysfunction at the time when therapy is begun. In patients with early CAN, reversibility is evident by power spectral analysis of HRV as early as 1 year after institution of strict control.⁶⁴

A randomized clinical trial in Japanese patients with T2DM showed that attainment of near-normal glycemia with intensive insulin therapy resulted in improvements in both postural hypotension and the coefficient of variation of R-R.⁶⁵ Defects in left ventricular sympathetic innervation can regress in diabetic subjects achieving good glycemic control.⁶⁶ The stepwise implementation of intensified multifactorial treatment slowed the progression to autonomic neuropathy in patients with T2DM and microalbumin-

FIGURE 46-1. The evaluation of postural dizziness.

uria.⁶⁷ Angiotensin-converting enzyme (ACE) inhibition restores HRV toward normal in those with mild abnormalities. Quinapril increases parasympathetic activity in patients with DAN. Therapies with ACE inhibitors increase vagal tone and decrease sympathetic tone.⁶⁸ This may in part explain the salutary effect in the Heart Outcomes Prevention Evaluation (HOPE) and microHOPE trials, in which the decrease in blood pressure was only 3/2 mmHg.^{69,70} In addition, a survey of evidence from clinical trials shows that early identification of autonomic neuropathy permits timely initiation of therapy with the powerful antioxidant α -lipoic acid, which slows or reverses progression of CAN.⁷¹

The progression of DAN may also be reversed by pharmacologic intervention with aldose reductase inhibitors.⁷² There is a beneficial effect of low-grade endurance training on HRV in the early stages of diabetic CAN.⁷³ Combined treatment with C peptide and insulin may improve respiratory HRV in patients with T1DM.⁷⁴ The cardioselective and lipophilic beta blockers might modulate the effects of autonomic dysfunction in diabetes (either peripherally by opposing the sympathetic stimulus or by a central acting mechanism) and thereby restore parasympathetic/sympathetic balance.⁷⁵

ORTHOSTATIC HYPOTENSION

Abnormal blood pressure regulation commonly accompanies autonomic neuropathy. The normal nighttime drop in blood pressure is reduced in patients with autonomic neuropathy. Orthostatic hypotension, another sign of autonomic neuropathy, is a fall

in systolic blood pressure of $(30 > \text{mmHg})$ upon standing due to damaged vasoconstrictor fibers, as well as impaired baroreceptor function and poor cardiovascular reactivity. This sign is accompanied by symptoms of dizziness, weakness, faintness, visual impairment, pain in the back of the head, and loss of consciousness (Fig. 46-1).

Two pathophysiologic states cause orthostatic hypotension: autonomic insufficiency and intravascular volume depletion. Physical examination and history should easily rule out volume depletion states. An important point is the exclusion of contributing factors that may be aggravating or unmasking the orthostatic hypotension of DAN. Prominent among these are volume depletion secondary to diuretics, excessive sweating, diarrhea, or polyuria. Other problems occur with antihypertensive medications, beta blockers, tricyclic antidepressants, and phenothiazines. Beta blockers impair heart rate responses, and the last two act through their α -adrenergic blocking properties to impair vasoconstriction.

Diagnosis

There are, however, a group of patients with contracted red cell mass who are not clinically dehydrated and who have orthostatic tachycardia.⁷⁶ They may develop modest tachycardia without a fall in pressure and have an exaggerated norepinephrine response.⁷⁷ They do respond to erythropoietin.⁷⁸ Of particular relevance is the observation that many people with this symptom complex become hypotensive with eating or within 10–15 minutes of taking their insulin injection. The symptoms, which are not unlike those of hypoglycemia, are often incorrectly ascribed to the hypoglycemic

action of insulin, but they occur too early and are actually due to a fall in blood pressure. This may be mediated by mild intravascular depletion secondary to increased capillary permeability caused by insulin or by its direct effect on the vasodilation of resistance vessels. Insulin may directly stimulate endothelial release of NO, a potent vasodilator, and may sensitize smooth muscle to the relaxant effects of prostacyclin and NO, thereby causing vasodilation unopposed by the action of norepinephrine.²⁸ Both an impaired vagal heart rate control and sympathetic nervous dysfunction exaggerate the hemodynamic effects of insulin in patients with diabetes, contributing to insulin-induced hypotension, which therefore tends only to occur with advanced autonomic neuropathy.⁷⁹

Treatment

Orthostatic hypotension in the patient with DAN can present a difficult management problem. Elevating the blood pressure in the standing position must be balanced against preventing hypertension in the supine position. Whenever possible, attempts should be made to increase venous return from the periphery using total body stockings. Patients should be instructed to put them on while lying down and not to remove them until returning to the supine position. Some patients with postural hypotension may benefit from treatment with 9-fluorohydrocortisone and supplementary salt 2–6 g daily. Unfortunately, symptoms do not improve until edema occurs, and there is significant risk of developing congestive heart failure and hypertension. If fluoro-hydrocortisone does not work satisfactorily, various adrenergic agonists and antagonists may be used. Patients may be treated with clonidine, which in this setting may paradoxically increase blood pressure. If the preceding measures fail, midodrine, an α adrenergic agonist may help.^{27,80} A particularly refractory form of orthostatic hypotension occurs in some patients postprandially and may respond to therapy with octreotide.⁸¹ Care should be taken to avoid higher doses, which could result in hypertension.

GASTROINTESTINAL AUTONOMIC NEUROPATHY

The gastrointestinal tract is innervated by extrinsic parasympathetic and sympathetic neurons and by intrinsic pathways (myenteric or Auerbach's and the submucosal or Meissner's plexus). Movement of food from mouth to the anus involves coordination of sympathetic, parasympathetic, plexus, and dopaminergic pathways. Sympathetic nervous system activity inhibits gastric emptying, parasympathetic nervous system activity stimulates gastric and esophageal peristalsis, and dopaminergic innervation inhibits gastric peristalsis. Neuropeptidergic function, e.g., glucose-dependent, insulin-releasing peptide (GIP) and somatostatin, plays a role in gastric emptying.⁸² An aberration in any of these pathways may result in abnormal gastrointestinal function.

Autonomic neuropathy can affect every part of the gastrointestinal tract, i.e., the esophagus, stomach, small intestine, and colon. Thus, the gastrointestinal manifestations are quite variable and include dysphagia, abdominal pain, nausea, vomiting, malabsorption, fecal incontinence, diarrhea, and constipation. Diabetic patients may present with a spectrum of manifestations from mild gastrointestinal symptoms to severe clinical disease.⁸³ The prevalence of symptoms caused by gastrointestinal dysfunction may reach 76% in a nonselected population of diabetic outpatients. Gastrointestinal tract symptoms and autonomic dysfunction are both

common in tertiary referral centers; however, symptoms and objective evidence of neuropathy are not always related.⁸⁴ Indeed, many gastrointestinal symptoms relate to depression rather than autonomic disease.⁸⁵

Esophageal Dysfunction

Esophageal motor disorders have been described in 75% of diabetic patients. Despite the frequent motility abnormalities described, symptoms of esophageal disease are rather uncommon in diabetics, and only approximately 30% experience symptoms. Motor abnormalities include impairment of peristaltic activity with double peak and tertiary contractions or impaired peristalsis and diminished lower esophageal sphincteric pressures. These factors may further predispose to gastroesophageal reflux disease, particularly in the setting of impaired gastric emptying. Esophageal dysfunction is detectable through esophageal motility testing and esophageal scintigraphy in diabetic patients.⁸⁶

Gastroparesis Diabeticorum

The prevalence of delayed gastric emptying in patients with longstanding diabetes is not known, due to a lack of population-based studies; it has been shown to occur in up to 50% of selected diabetic patients.⁸⁷ It is usually clinically silent, although severe diabetic gastroparesis is one of the most debilitating of all the gastrointestinal complications of diabetes.

Physiology of gastric emptying largely depends on vagus nerve function, which may be grossly disturbed in diabetes. The gastric basal electrical rhythm is initiated by the pacemaker and is conducted circumferentially and longitudinally toward the pylorus. The gastric pacemaker area is located in a region at the junction of the fundus and body on the greater curvature. The interdigestive motor activity of the stomach during fasting is divided into four phases; during the peak activity of the third phase (the migrating motor complex [MMC]), the stomach bursts into contractions with a frequency of three contractions a minute. Liquid emptying is controlled by the fundus and depends on the volume of gastric contents. With impaired vagal function, the proximal stomach is less relaxed, and liquid emptying may actually be faster than normal in diabetic patients. Solid-phase emptying is caused by powerful contractions of the antrum. These contractions grind and mix solid food into particles of <1 mm in size, which then pass through the pylorus into the duodenum. Phase three contractions of the interdigestive MMC are frequently absent in diabetic patients. This results in poor antral grinding and emptying, which may result in gastric retention. Furthermore, there may be disordered integration of gastric and duodenal motor function resulting from disturbances in receptor relaxation of the stomach. Pylorospasm may occur because of disturbed contractility, which causes a functional resistance to gastric outflow. Impaired gastric emptying puts the patient at particular risk for gastric bezoars formation.

The exact pathophysiology of gastric motor disturbances is not certain. It is clear that vagal parasympathetic dysfunction disturbances may occur. The release of the peptide motilin, which regulates gastrointestinal motility, is under vagal control. Motilin stimulates initiation of phase 3 motor activity of the MMC of the stomach and will do so in patients with gastroparesis. Hyperglycemia itself may cause delayed gastric emptying of liquids and solids in both diabetic and healthy individuals.⁸⁸ Gastric dysrhyth-

mias, known as functional pathology, are defined as bradygastria and tachygastria. Gastric dysrhythmias have been found in 100% of diabetic patients with meal-related symptoms. Gastric dysrhythmias interfere with the normal gastric peristaltic contractions. Loss of vagal tone and increased sympathetic nervous system activity have been associated with gastric dysrhythmias. Acute hyperglycemia can evoke tachygastria and suppress antral contractions.

The typical symptoms of diabetic gastroparesis are early satiety, nausea, vomiting, abdominal bloating, epigastric pain, and anorexia (Fig. 46-2). Patients with gastroparesis have emesis of undigested food consumed many hours or even days previously. Episodes of nausea and vomiting may last for days to months or occur in cycles.⁸⁹ Even with mild symptoms, gastroparesis interferes with nutrient delivery to the small bowel and therefore disrupts the relationship between glucose absorption and exogenous insulin administration. This may result in wide swings of glucose levels and unexpected episodes of postprandial hypoglycemia and "brittle diabetes." Gastroparesis should therefore always be suspected in patients with erratic glucose control. Upper gastrointestinal symptoms should not be attributed to gastroparesis until conditions such as gastric ulcer, duodenal ulcer, gastritis, and gastric cancer have been excluded.

Diagnosis

Scintigraphy is generally regarded as the reference method in the evaluation of disordered gastric emptying in diabetic patients. The measurement of gastric emptying of solids is more sensitive than that of liquids. Hyperglycemia exerts a major influence on gastric motor function in that it slows gastric emptying in diabetic patients. The [¹³C]octanoic acid breath test represents a suitable measure of delayed gastric emptying in diabetic patients, which is associated with the severity of gastric symptoms but is not affected by the blood glucose level.⁹⁰

Treatment

Initial treatment of diabetic gastroparesis should focus on blood glucose control. Physiologic control of blood glucose levels may improve gastric motor dysfunction. The management of gastroparesis should include multiple small feedings with a reduction in the fat content (<40 g/day), which tends to delay gastric emptying. A low-fiber diet is also advised in diabetic gastroparesis to avoid bezoar formation. Metoclopramide, domperidone and levosulpride offer potential therapy in the management of gastroparesis. Metoclopramide is a cholinergic and antidopaminergic agent with central antiemetic activity.⁹¹ Central nervous system side effects such as tremor, restlessness, tardive dyskinesia, and drowsiness limit the use of metoclopramide. Other side effects observed with metoclopramide are galactorrhea and hyperprolactinemia. The recommended dosage is 10 mg four times a day, 30–60 minutes before meals and at bedtime. Metoclopramide may be given intravenously or as a liquid or suppository. The drug will not be absorbed when given orally if large gastric residuals secondary to severe gastroparesis are present. In this instance, gastric suctioning and intravenous nutrition, as well as intravenous drug administration, are needed until the stomach begins to empty, at which time oral therapy can be reinstituted. Tachyphylaxis occurs and requires that the drug be stopped temporarily and then restarted.

Domperidone is a peripherally acting dopamine 2-receptor antagonist without cholinergic activity. Domperidone has direct antiemetic activity. Domperidone improves gastrointestinal motility by enhancing antral concentrations. Central nervous side effects are observed less frequently with domperidone than with metoclopramide. The oral dose of domperidone for the treatment of gastroparesis is 20–40 mg, four times a day, taken 30 minutes before meals and, if necessary, at bedtime.

Levosulpride is a new prokinetic drug that is a selective antagonist for D₂-dopamine receptors. Recent studies have suggested that patients receiving this medication, given at a dosage of 25 mg

FIGURE 46-2. The evaluation of a patient with gastroparesis diabeticorum.

3 times per day orally, show maintained improvement in gastric emptying and improved glycemic control.

Erythromycin exerts its effect by stimulation of motilin receptors. Erythromycin and its derivatives have improved gastric emptying of solids and liquids and increased antral contraction.^{92,93} Erythromycin may cause nausea, abdominal cramps and diarrhea, rash, and allergic manifestations. The oral dose of erythromycin is 250 mg three times daily, taken 30 minutes before meals. Intravenous erythromycin (3 mg/kg/every 8 hours by infusion) is a useful drug for clearance of gastric bezoars. The gastrokinetic efficacy of metoclopramide, domperidone, and erythromycin diminishes during prolonged administration.

If medications fail and severe gastroparesis persists, jejunostomy placement into normally functioning bowel may be needed. Satisfactory relief of intractable vomiting from diabetic gastroparesis is achieved by a percutaneous endoscopic gastrotomy (PEG) or novel radical surgical procedure.^{94,95}

Diabetic Diarrhea

Diarrhea may be evident in 20% of diabetic patients, particularly those with known autonomic neuropathy. However, the prevalence of chronic diarrhea in a nonselected heterogeneous diabetic population is 3.7%. Diabetic diarrhea is more common among T1DM than T2DM patients.⁹⁶ A number of factors may contribute to the diarrhea, including stasis of bowel contents with bacterial overgrowth, bile acid-induced intestinal hurry, and malabsorption, as well as a diminution in pancreatic exocrine secretions, presumably due to the need for insulin to maintain exocrine pancreatic function and the vagal pancreatic neuropathy. The most frequent cause of chronic nondiabetes-provoked diarrhea has been found to be metformin.⁹⁶

Diagnosis

Autonomic neuropathy-associated diarrhea can be sudden, explosive, nocturnal, and paroxysmal. It is characterized by stool volumes greater than 300 g/day and up to 10–20 bowel movements per day. Fecal incontinence may be associated with severe diabetic diarrhea or may constitute an independent disorder of anorectal dysfunction. Incontinent diabetics have decreased basal sphincteric tone, suggesting abnormal internal and external anal sphincter function.

Treatment

The severe and intermittent nature of diabetic diarrhea makes treatment and assessment difficult. Because afferent denervation may contribute to the problem, a bowel program that includes regular efforts to move the bowels is indicated. Initial therapy of diabetic diarrhea should be directed toward correction of electrolyte/water disturbances and nutrition. Good control of glucose levels is helpful. Treatment should be directed at the identified cause of diabetic diarrhea. A broad-spectrum antibiotic (doxycycline and metronidazole) is usually the treatment of choice for bacterial overgrowth. Retention of bile sometimes occurs, which may be highly irritating to the gut, and chelation of bile salts with 4-g tid cholestyramine mixed with fluid and given orally may be of considerable help. Antidiarrheal agents (loperamide and diphenoxylate) can reduce the number of stools. However, toxic megacolon can occur, and extreme care should be used.

Clonidine may restore adrenergic nerve dysfunction and improve diarrhea. Initial treatment should begin with 0.1 mg twice a

day. Clonidine may cause orthostatic hypotension. Topical clonidine may also control diarrhea without causing orthostatic hypotension. Octreotide slows motility and inhibits the release of gastroenteropancreatic endocrine peptides, which may be pathogenetic factors responsible for diarrhea and electrolyte imbalance in diabetic patients. Octreotide has been shown to be effective in improving diarrhea at a dose of 50–75 μ unit = μ g sc twice a day.⁹⁷

Constipation

The most common problem associated with diabetic gastrointestinal dysfunction is constipation. Severe constipation may be complicated by ulceration, perforation, and fecal impaction. Precipitous change in bowel habits should prompt colonic evaluation to exclude the possibility of neoplasm and stricture.⁹⁸ The most commonly reported drug class associated with constipation in persons with diabetes mellitus is calcium channel blockers. The use of amitriptyline for neuropathic pain is an important cause of constipation in these patients because of its anticholinergic properties. For this reason other agents should be selected.

Treatment

Treatment for constipation should begin with emphasis on good bowel habits, which include regular exercise and maintenance of adequate hydration and fiber consumption. Many constipated patients respond to a high-soluble-fiber diet supplemented with daily hydrophilic colloid. Sorbitol and lactulose may be helpful. MetamucilTM may soften stools, and metoclopramide stimulates colorectal activity. Nonetheless, periodic enemas may be needed, and the anticholinergic drugs used for peripheral neuropathy must be avoided.

Gall Bladder Atony

In diabetic patients with autonomic neuropathy, gallbladder contraction is reduced, because of impaired vagal function. Autonomic neuropathy of the gallbladder results in a stasis of bile salts that may “spill over” into the intestines at inappropriate times. The atony and elevation of cholesterol frequently seen in diabetic patients predispose these patients to cholelithiasis.

Treatment is usually surgical at the time of presentation. However, in patients placed on lithogenic drugs, e.g., somatostatin, ultrasonography is advised prior to starting therapy, with prophylactic stone removal.

GENITOURINARY AUTONOMIC NEUROPATHY

Erectile Dysfunction

The most common form of organic sexual dysfunction in male diabetics is erectile dysfunction (ED). ED is defined as the consistent inability to attain and maintain an erection adequate for sexual intercourse, usually qualified by being present for several months and occurring at least half the time. The incidence of ED in diabetic men has been estimated to be between 35 and 75%.⁹⁹

The etiology of ED in diabetes is multifactorial. Neuropathy, vascular disease, metabolic control, nutrition, endocrine disorders, psychogenic factors, and drugs used in the treatment of diabetes and its complications play a role. ED is a marker for the develop-

ment of generalized vascular disease and for premature demise from a myocardial infarct, and penile failure may be a portent of upcoming, and possibly preventable, cardiovascular events.¹⁰⁰ Thus, ED in diabetics should alert the physician to perform cardiovascular evaluation.

The relationships among the sympathetic and parasympathetic nervous systems, the endothelium, and smooth muscle function may be disrupted by diseases of blood vessels or nerves, such as occurs in diabetes. In diabetes, the development of autonomic neuropathy is partly responsible for the loss of cholinergic activation of the erectile process. In the penis, acetylcholine acts on the vascular endothelium to release NO and prostacyclin, both of which are defective in diabetes. There is also evidence that nonadrenergic/noncholinergic nerve function is hampered, with decreased content of VIP, SP, and other neuropeptide vasodilator neurotransmitters.

The symptoms of organic ED are gradual in onset and progress with time. The earliest complaints are decreased rigidity with incomplete tumescence before total failure. It occurs with all partners, and there is no loss of libido. Morning erections are lost. Sudden loss of erections with a particular partner, while maintaining morning erections and nocturnal penile tumescence, suggest a psychogenic cause. However, psychogenic factors may be superimposed on organic dysfunction in diabetes.

Diagnosis

Evaluation of diabetic men with erectile dysfunction is complex (Fig. 46-3). Initial assessment of patients with ED should be carried out in the presence of their significant other or sexual partner, if possible. Health care providers should make an attempt to inter-

FIGURE 46-3. The evaluation of a diabetic patient with erectile dysfunction. NPT, nocturnal penile tumescence.

view the partner to obtain an impression of the overall relationship and the impact that the return of erections will have on the relationship. Extreme care must be exercised in these situations; in many instances a patient's desire is to be able to have erections but not necessarily to actually have sexual relations.

A thorough work-up for impotence will include medical and sexual history; physical and psychological evaluation; blood tests for diabetes and for testosterone, prolactin, and thyroid hormone levels; test for nocturnal erections (absence of erections during sleep suggests a physical cause of impotence); tests to assess penile, pelvic, and spinal nerve function; and a test to assess penile blood supply and blood pressure. The flow chart provided (Fig. 46-3) is intended as a guide to assist in defining the problem.

The health care provider should initiate questions that will help distinguish the various forms of organic erectile dysfunction from those that are psychogenic in origin. In all instances, a careful history must be taken to determine the rapidity of onset of ED, presence of morning erections, uniformity of sexual dysfunction with all partners, evidence of autonomic nervous dysfunction, vascular insufficiency, hormonal inadequacy, and drugs used in the treatment of satellite disorders.

Physical examination must include an evaluation of the autonomic nervous system, vascular supply, and the hypothalamic-pituitary-gonadal axis.

Autonomic neuropathy causing ED is usually accompanied by loss of ankle jerks and absence or reduction of vibration sense over the large toes. More direct evidence of impairment of penile autonomic function can be obtained by demonstrating normal perianal sensation, assessing the tone of the anal sphincter during a rectal exam, and ascertaining the presence of an anal wink when the area of the skin adjacent to the anus is stroked or contraction of the anus when the glans penis is squeezed, i.e., the bulbo-cavernosus reflex. These measurements are easily and quickly done at the bedside and reflect the integrity of sacral parasympathetic divisions. More sophisticated testing of the autonomic nervous system can be done by measuring the change in postural blood pressure and the change in heart rate with deep breathing.

Vascular disease is usually manifested by buttock claudication but may be due to stenosis of the internal pudental artery. A penile/brachial index of <0.7 indicates diminished blood supply. A venous leak manifests as unresponsiveness to vasodilators and needs to be evaluated by penile Doppler sonography.

To distinguish psychogenic from organic erectile dysfunction, nocturnal penile tumescence (NPT) testing can be done. Normal NPT defines psychogenic ED, and a negative response to vasodilators implies vascular insufficiency. Application of NPT testing is not so simple. It is much like having a sphygmomanometer cuff inflate over the penis many times during the night while one is trying to have a normal night's sleep including the REM sleep associated with erections. The individual may have to take the device home and become familiar with it over several nights before a conclusion is reached that NPT testing has failed.

Integrity of the penile vasculature is assessed by quantitation of blood flow in response to the potent vasodilator prostaglandin E (alprostadil, 20 μ g) given directly into the corpora cavernosa. In patients with psychogenic impotence, erections can be obtained virtually 100% of the time. Similarly, in neurogenic impotence, the response to intracavernosal injection is about 95%. Failure of response implies vascular insufficiency, either arterial or venous in-

competence. It is not surprising that patients with diabetes respond about 65–70% of the time, in keeping with a predominantly neurogenic cause of their ED and compatible with a significant arterial component.

Treatment

A number of treatment modalities are available, each with positive and negative effects; therefore patients must be made aware of both aspects before a therapeutic decision is made. Before considering any form of treatment, every effort should be made to have the patient withdraw from alcohol and eliminate smoking. First and foremost, the patient should be removed, if possible, from drugs that are known to cause erectile dysfunction (Table 46-3). Only three classes of antihypertensives are relatively infrequently associated with erectile dysfunction: α_1 -adrenergic blockers, ACE inhibitors, and calcium channel blockers. Metabolic control should be optimized. Direct injection of prostacylin into the corpus cavernosum will induce satisfactory erections in a significant number of men. Also, surgical implantation of a penile prosthesis may be appropriate. The less expensive type of prosthesis is a semirigid, permanently erect type that may be embarrassing and uncomfortable for some patients. The inflatable type is three times more expensive and is subject to mechanical failure, but it avoids the embarrassment caused by other devices.

According to more recent research, relaxation of the corpus cavernosus smooth muscle cells is caused by NO and cGMP, and the ability to have and maintain an erection depends on NO and cGMP. Sildenafil exerts its effect by transiently increasing NO and cGMP levels. Sildenafil is a GMP type-5 phosphodiesterase inhibitor that enhances blood flow to the corpora cavernosae with sexual stimulation. A 50-mg tablet taken orally is the usual starting dose, 60 minutes before sexual activity. Lower doses should be considered in patients with renal failure and hepatic dysfunction. The duration of the drug effect is 4 hours. Before the drug is prescribed, it is important to exclude ischemic heart disease. It is absolutely contraindicated in patients being treated with nitroglycerine or other nitrate-containing drugs. Severe hypotension and fatal cardiac events can occur.¹⁰¹

TABLE 46-3. Drugs known to cause erectile dysfunction and commonly used in diabetic patients

Antihypertensive agents
Beta-blockers
Thiazide diuretics
Spironolactone
Methyldopa
Reserpine
Agents acting on the central nervous system
Phenothiazines
Haloperidol
Tricyclic antidepressants
Drugs acting on the endocrine system
Estrogens
Antiandrogens
Gonadotropin antagonist
Spironolactone
Cimetidine
Metoclopramide
Fibric acid derivatives
Alcohol
Marijuana

Retrograde Ejaculation

Retrograde ejaculation is caused by damage to efferent sympathetic innervations, which coordinate the simultaneous closure of the internal vesicle sphincter and relaxation of the external vesicle sphincter during ejaculation. Retrograde ejaculation is reported to occur in up to 32% of diabetic men. Lack of spermatozoa in the semen and the presence of motile sperm in a postcoital specimen of urine confirm the diagnosis. Diabetic patients with retrograde ejaculation will require help if pregnancy is to be achieved.

Female Sexual Dysfunction

Despite the severe ravages of autonomic neuropathy on the urogenital system, females with this condition do not suffer from loss of libido and orgasm. Parasympathetic function mediates vaginal lubrication, and, in general, the parasympathetic nervous system is selectively impaired in females with diabetes mellitus. Approximately 30% of diabetic women have some degree of sexual dysfunction. Women with diabetes mellitus have decreased vaginal lubrication, which may lead to vaginal wall atrophy and dyspareunia.¹⁰²

Diagnosis

The diagnosis of female sexual dysfunction requires a conscientious effort to elicit a history of dyspareunia, the use of vaginal lubricants, or both. The value of diagnosis of female sexual dysfunction using vaginal plethysmography to measure lubrication and vaginal flushing has not been well established. Therapy may include use of lubricating agents or estrogen creams.

Treatment

An estrogen cream has the advantage of not only providing the necessary lubrication but also thickening the vaginal walls, thereby possibly decreasing dyspareunia.

Cystopathy

Neural impairment of the bladder includes sympathetic, parasympathetic, and pudental nerves. Efferent parasympathetic fibers promote bladder contraction during urination. Efferent sympathetic fibers maintain sphincter tone between urinations and decrease their activity during urination. Afferent autonomic fibers transmit sensation of bladder fullness. In DAN, the motor function of the bladder is unimpaired, but afferent fiber damage results in diminished bladder sensation.

The urinary bladder can be enlarged to more than three times its normal size. Patients are seen with bladders filled to their umbilicus, yet they feel no discomfort. Loss of bladder sensation occurs early in DAN, with diminished voiding frequency, and the patient is no longer able to void completely. Consequently, dribbling and overflow incontinence are common complaints. Autonomic neuropathy-associated neurogenic bladder dysfunction may manifest as partial or complete urinary retention, incontinence, or frequent urination including nocturia. Chronic neurogenic bladder can cause vesicoureteric reflux with renal damage. In addition, chronic dysfunction also causes inadequate emptying, with consequent urinary infection. More than two urinary tract infections per year should alert the physician to possible cystopathy and should elicit appropriate diagnostic procedures.

Diagnosis

A postvoiding residual of greater than 150 cc is diagnostic of abnormal bladder function and may be detected by several methods: postvoiding sonography, cystometrogram, postvoiding catheterization, or postvoiding intravenous pyelogram (IVP), which may be injurious to the diabetic kidney. Postvoiding sonography can accurately and noninvasively evaluate the residual urine retained within the bladder. Postvoiding catheterization is invasive and may produce bacteriuria. A cystometrogram is the procedure of choice for evaluating both afferent and efferent bladder function.

Treatment

The principal aims of treatment are improvement of bladder emptying and reduction of risk of urinary tract infection. Patients with cystopathy should be instructed to palpate the bladder and, if they are unable to initiate micturition when the bladder is full, use Crede's maneuver to start the flow of urine every 4 hours. Parasympathomimetics such as bethanechol (10–30 mg three times a day) are sometimes helpful, although frequently they do not help to empty the bladder fully. Extended sphincter relaxation can be achieved with an α_1 -blocker such as doxazosin. Self-catheterization can be particularly useful in this setting, with the risk of infection generally being low. If α_1 -blockade fails in males, bladder neck surgery may help to relieve spasm of the internal sphincter. Because the somatic supply of the external sphincter remains intact, continence is preserved.

IMPAIRED SKIN BLOOD FLOW

Skin blood flow is important in maintaining nutrition and regional and whole-body temperature and in healing traumatized skin. There are two different types of skin. The first is apical (glabrous) skin, which is present in the palmar surface of the hand, plantar surface of the foot, and the face. Apical skin contains a large number of AV anastomoses or AV shunts and functions in thermoregulation. In contrast, nonapical (hairy) skin is present over most of the body surface. There are relatively few AV shunt vessels, and blood flow is primarily nutritive in function. Microvascular skin flow is under the control of the ANS and is regulated by both the central and peripheral components of the ANS. AV shunts provide a potential low-resistance pathway by which blood flow can be diverted from the arteriolar to the venular circulation, bypassing the capillary bed. The shunts are maintained in a constricted state by sympathetic tone. Loss of this tone due to neuropathy causes the shunts to open, and consequent deviation of blood flow from the skin. Increased venular oxygen levels, apparent ischemic lesions despite the presence of palpable pulses, and raised skin temperatures in the distal extremities are consistent with AV shunting.

In diabetes, the rhythmic contraction of arterioles and small arteries is disordered. Defective blood flow in the small capillary circulation is found, with decreased responsiveness to mental arithmetic, cold pressor, handgrip, and heating (Fig. 46-4). The defect is associated with a reduction in the amplitude of vasomotion and resembles premature aging.^{103,104}

There are differences in the glabrous and hairy skin circulations. The vessels in the dorsum of the hand show a moderate endothelial defect and a profound inability to dilate with heat and the added hydrostatic gradient of lowering the limb (Fig. 46-5). In hairy skin, a functional defect is found prior to the development of

FIGURE 46-4. Impaired skin blood flow in diabetic patients. (Reproduced with permission from Stansberry et al.¹⁰⁴)

neuropathy.¹⁰⁵ The factors that contribute to the development of foot ulceration include loss of cutaneous sensitivity to pain and warm thermal stimulation; impairment of sweating with dryness and cracking of the skin; and defective autonomic function with a decrease in blood flow that compromises nerve function and also impairs the supply of essential nutrients and tissue perfusion. It is this constellation that engenders the perfect milieu for the development of foot ulceration and gangrene (see Chap. 51).

Charcot foot may present acutely with severe pain, a warm to hot foot with increased blood flow (despite decreased warm sensory perception and vibration detection), and clear evidence of acute osteopenia.¹⁰⁶⁻¹⁰⁸ An important factor in the development of Charcot joints is equinovarus deformity caused by Achilles tendon shortening.¹⁰⁹ The repetitive trauma in the Charcot foot increases osteoclastic activity and blood flow, with consequent osteopenia.¹¹⁰

The osteopenia predisposes the small bones of the foot to small fractures with minimal provocation, especially with the development of equines.

The development of neurovascular dysfunction in diabetic patients involves complex and multifactorial processes. There are three key elements: endothelium, smooth muscle, and nerve supply. Evaluation of each component is essential to understanding the neurovascular dysfunction of diabetes mellitus. The vascular endothelium has a key role in the pathogenesis of microangiopathy and neuropathy by producing important chemicals such as NO, endothelin, and prostacylin.

Diagnosis

The advantage of noninvasive methods for assessing skin blood flow has allowed clinical measurements of the effects of dia-

FIGURE 46-5. Abnormal blood flow in hairy skin on dorsum of hand in patients with type 2 diabetes. (Reproduced with permission from Stansberry et al.¹⁰⁵)

betes on neurovascular dysfunction. Microvascular blood flow can be accurately measured noninvasively using laser Doppler flowmetry under basal and stimulated conditions. Smooth muscle microvasculature in the periphery reacts to a number of stressor tasks. These may be divided into those dependent on the integrity of the central nervous system—orienting response and mental arithmetic—and those dependent on the distal sympathetic axon—handgrip and cold pressor tests.

Treatment

Drying between the toes after bathing and application of softening creams are critical measures for the prevention of foot ulcers. Daily inspection of the feet is paramount, and patients must be taught proper toenail-cutting techniques. A few studies have examined the ability to alter blood flow in diabetes. In animal models, NGF increases blood flow, but data are not available in humans.¹¹¹ A prostaglandin analog, cilastazol, may benefit some people.¹¹² Altering the rheology of red blood cell viscosity using pentoxifylline has proved disappointing.¹¹³ Increasing substrate availability for NO generation by ingestion of arginine helps patients with Raynaud's disease, but there are no reports in diabetes mellitus. Changing sensitivity to NO appears to occur with ACE inhibitors and the glitazones, possibly by their action on insulin resistance, but their role needs to be defined.^{114,115}

SUDOMOTOR DYSFUNCTION

Hyperhidrosis of the upper body, often related to eating (gustatory sweating) and anhidrosis of the lower body, is a characteristic feature of autonomic neuropathy. Unless carefully elicited, a history of abnormal sweating pattern and distal anhidrosis is often unrecognized. Gustatory sweating is thought to be due to axonal regeneration within the autonomic nervous system.¹¹⁶ Gustatory sweating is much more common among diabetic patients with neuropathy and especially nephropathy. The hyperhidrosis, cracked and dry skin, and increased small blood vessel flow due to autonomic dysfunction create an excellent milieu for infection to take hold and proliferate. Infection develops after skin breaks down and, combined with ischemia, can eventually lead to gangrene.

Treatment

Sudomotor disturbance may respond to treatment with propantheline hydrobromide as scopolamine patches. Anticholinergic drugs have been used successfully for the treatment of gustatory sweating, but anticholinergic agents may be less well tolerated than the condition itself. There is a suggestion that application of glycopyrrrolate (an antimuscarinic compound) might benefit diabetic patients with gustatory sweating.¹¹⁷ Intradermal injection of botulinum toxin A is also effective treatment for excessive sweating.¹¹⁸ Special attention must be paid to foot care. The diabetic patient must pay particular attention to appropriate footwear, padded socks, and hydrating creams.

HYPOGLYCEMIA UNAWARENESS

The counterregulatory hormone responses and awareness of hypoglycemia are reduced in patients with long-standing T1DM (see Chap. 31). The glucagon response is impaired with diabetes duration of 1–5 years, and after 14–31 years of diabetes, the glucagon

response is almost undetectable. The release of catecholamine alerts the patient to take the required measures to prevent coma due to low blood glucose. The absence of warning signs of impending neuroglycopenia is known as **hypoglycemic unawareness**. Hypoglycemic unawareness should not, however, be used as a criterion to make the diagnosis of autonomic neuropathy because it may also occur in diabetes as a result of improved glycemic control in conjunction with recurrent antecedent hypoglycemia. The combined autonomic deficit in heart rate and blood pressure responses to standing is associated with a modest increase in the risk of severe spontaneous hypoglycemia.¹¹⁹

Treatment

Patients with hypoglycemia unawareness and unresponsiveness pose a significant management problem for the physician. Although autonomic neuropathy may improve with intensive therapy and normalization of blood glucose, there is a risk to the patient, who may become hypoglycemic without being aware of it and who cannot mount a counterregulatory response. It is our recommendation that if a pump is used, boluses of smaller than calculated amounts should be used; if intensive conventional therapy is used, long-acting insulin with smaller boluses should be given. One should be cautious about attempting to aim for normal glucose and HbA_{1c} levels in these patients and take care to avoid the possibility of hypoglycemia.¹²⁰ A remarkable reduction in the frequency of severe hypoglycemia can be achieved with hypoglycemia awareness training.¹²¹

PUPILLARY ABNORMALITIES

The pupillary iris is dually innervated by parasympathetic and sympathetic fibers. Parasympathetic fibers mediate pupillary constriction, whereas sympathetic fibers mediate pupillary dilation. The sympathetic fibers are most often regulated by changes in arousal, whereas the parasympathetic fibers are activated mainly by change in light intensity. Patients with DAN show delayed or absent reflex response to light and diminished hippus, accounted for by decreased sympathetic activity and a reduced resting pupillary diameter. Autonomic neuropathy of the pupil is often apparent on routine eye examination but can be confirmed by more sophisticated testing using a pupillometer.¹²²

Treatment

The pupillary abnormalities do not tend to produce any significant functional defect, except for potential failure of dark adaptation and difficulty with driving at night. Patients should therefore be warned about driving at night.¹²³

RESPIRATORY DYSFUNCTION

Respiratory reflexes may be impaired in diabetic patients with autonomic neuropathy. Ventilatory responses to hypoxia and hypercapnia are reduced in DAN.¹²⁴ Parasympathetic dysfunction can cause reduced airway tone. Obstructive sleep apnea is more prevalent in diabetic patients with autonomic neuropathy than in those without.¹²⁵ Nasal continuous positive airway pressure is an effective therapy for obstructive sleep apnea syndrome.¹²⁶ A temporal relationship between sudden cardiac arrest and interference with normal respiration by hypoxia, drugs, or anesthesia has

been reported.¹²⁴ Sudden cardiopulmonary arrest in diabetic patients with cardiac autonomic neuropathy may be of respiratory origin due to loss of hypoxic respiratory drive.

DEAD IN BED

The undetected autonomic dysfunction, when associated with nocturnal hypoglycemia, may predispose T1DM patients to fatal ventricular dysrhythmia constituting the **dead in bed syndrome**.¹²⁷ Possible mechanisms of sudden death are silent ischemia, prolonged QT interval predisposing to ventricular arrhythmias, or abnormal central control of breathing.

SUMMARY

DAN is an extremely important clinical disorder. Although involvement of the ANS is generally diffuse, symptoms may be confined to a single target organ or organ system. Complications affecting these systems contribute greatly to the morbidity, mortality, and reduced quality of life and activities of daily living of the person with diabetes. They are also the major source of increased costs of caring for the diabetic patient. Factors in the pathogenesis are metabolism, vascular insufficiency, loss of growth factor trophism, and autoimmune destruction of nerves in a visceral and cutaneous distribution. We have reviewed the variety of clinical manifestations associated with autonomic neuropathy and have discussed current views related to the symptomatic management of the different abnormalities. Our ability to manage the many different manifestations of DAN successfully depends ultimately on our success in uncovering the pathogenetic processes underlying this disorder and directing therapies at the cause rather than the manifestations. There are also studies in progress suggesting that autonomic nerves can be induced to regenerate, and the future for patients with DAN is less bleak than hitherto perceived.

Diabetic Dyslipidemia: Pathophysiology and Treatment

Clay F. Semenkovich

For people with both type 1 and type 2 diabetes mellitus (T1DM and T2DM), the risk of premature death due to atherosclerosis is considerable. Atherosclerosis and its complications account for about 80% of mortality in diabetes. Dyslipidemia is common in diabetic patients and is probably a major contributor to the initiation and propagation of atherosclerotic lesions in these patients. Because of poorly understood interactions between the diabetic state and dyslipidemia, the effects of disturbances in circulating lipid levels are amplified in diabetes. Even modest abnormalities of circulating lipoproteins in diabetics disproportionately increase vascular risk. Since diabetic patients without known coronary artery disease appear to have the same risk for myocardial infarction as nondiabetic patients with previous myocardial infarction,¹ an aggressive approach to lipid management should be considered in every patient with diabetes.

EPIDEMIOLOGY

In poorly controlled T1- and T2DM, patients have elevated levels of triglycerides, low levels of high-density lipoprotein (HDL) cholesterol, and changes in the composition of low-density lipoprotein (LDL) cholesterol that may substantially enhance the atherogenic potential of this particle.

Regardless of the type of diabetes, the hallmark of diabetic dyslipidemia is hypertriglyceridemia. In a compilation of studies comparing mean lipid levels from treated diabetic patients with those from controls matched for age and weight,² plasma triglyceride levels were increased in both T1- and T2DM, and HDL cholesterol was decreased in people with T2DM (Fig. 47-1). In the World Health Organization (WHO) multinational study,³ serum triglyceride concentrations were related to macrovascular risk using five national sample sets. Triglycerides were more strongly associated with ischemic heart disease than cholesterol. Data from the Multiple Risk Factor Intervention Trial⁴ and the Paris Prospective Study⁵ also indicate that triglyceride levels better predict vascular risk than total or LDL cholesterol in diabetes. Triglyceride levels increase and HDL cholesterol levels decrease continuously as glucose intolerance increases in nondiabetic cohorts.⁶ These data suggest that dyslipidemia predating the development of overt T2DM contributes to the high frequency of coronary heart disease present in these patients at the time of initial diagnosis.

In 1979, the Framingham Study first reported that premenopausal women with diabetes have the same risk for vascular disease as diabetic men,⁷ suggesting that the protective effect of being female with respect to heart disease is negated by diabetes.

This observation has been confirmed in economically and racially diverse populations ranging from Evans County, Georgia,⁸ to Rancho Bernardo, California.⁹ Over the past 30 years, coronary heart disease mortality in the United States has declined for the general population but not for women with diabetes. Recent data from National Health and Nutrition Examination Surveys show that age-adjusted heart disease mortality has declined 27% for nondiabetic women but increased 23% in diabetic women.¹⁰ Smaller declines in mortality were seen for diabetic compared with nondiabetic men.

The poor prognosis for women with diabetes may be explained in part by the effects of diabetes on dyslipidemia in women. The Prospective Cardiovascular Munster study (PROCAM), involving over 50,000 German men and women, reported that diabetic women were more likely than diabetic men to manifest dyslipidemia, especially low HDL cholesterol.¹¹ The Strong Heart Study is a population-based study of vascular disease that includes over 1400 females and over 800 males with diabetes. In this group, diabetic women compared with their male counterparts had greater decreases in HDL cholesterol and apolipoprotein A1 (apoA1; the major protein component of HDL particles) and greater increases in apolipoprotein B (apoB; the major protein component of atherogenic lipoproteins like very-low-density lipoprotein [VLDL], intermediate-density lipoprotein [IDL], and LDL), and greater decreases in the size of LDL particles.¹²

The composition of LDL particles is frequently abnormal in people with diabetes. The most commonly described abnormality is small, dense LDL, a particle that may be particularly atherogenic. In case-control studies of nondiabetics from the Stanford Five-City Project¹³ and the Physicians' Health Study,¹⁴ small, dense LDL was shown to be associated with coronary artery disease. The presence of the small LDL phenotype is inversely related to triglyceride levels. Patients with T2DM and insulin resistance have a preponderance of small, dense LDL. T1DM subjects from the Pittsburgh Epidemiology of Diabetes Complications Study¹⁵ and the Diabetes Control and Complications Trial (DCCT)¹⁶ had an increased frequency of the small, dense LDL phenotype, especially in the setting of renal dysfunction.

Although LDL cholesterol levels are usually not classified as elevated in people with diabetes, these "normal" LDL cholesterol levels should be considered elevated given the effects of moderate hyperlipidemia in the setting of diabetes. The mean LDL cholesterol level was 109 mg/dL for people with T2DM in the Strong Heart Study. Even at these low levels, LDL cholesterol was a significant independent predictor of vascular disease, with risk increasing linearly from an LDL cholesterol concentration of 70 mg/dL. In the United Kingdom Prospective Diabetes Study (UKPDS

FIGURE 47-1. Plasma lipid levels in treated type 1 and type 2 diabetic patients. Values were obtained from 22 different studies in which age- and weight-matched diabetics were compared with a control group. Each point represents mean values of diabetics divided by mean values of controls. (Reproduced with permission from Kern.²)

the mean LDL cholesterol level was 128 mg/dL for men and 147 mg/dL for women. Even at these relatively "normal" levels, LDL cholesterol was a powerful predictor of coronary artery disease in UKPDS.¹⁸

GLYCEMIC CONTROL AND DYSLIPIDEMIA

Poor glucose control clearly exacerbates dyslipidemia. Improved glycemic control in both T1- and T2DM improves dyslipidemia. However, most of the improvement in lipid levels occurs after early routine measures to improve diabetic control rather than later after intensive adjustment of hypoglycemic medications.

Glucose promotes hepatic lipogenesis. Since the flux of glucose through the liver is increased in T2DM, glucose alone can increase lipid content and promote dyslipidemia. Glucose can also modify lipoproteins. Like hemoglobin, which becomes glycosylated to form a marker for chronic glycemic control, components of lipoproteins like apoB can become glycosylated. Because the extent of glycosylation is determined by circulating glucose concentrations, it is not surprising that more apoB molecules are glycosylated in LDL from subjects with diabetes compared with nondiabetics. Advanced glycation end products are also found in lipoproteins from people with diabetes.¹⁹ These compositional changes interfere with the clearance of LDL by the LDL receptor and prolong its residence time in the circulation. Glycooxidation of LDL in the vessel wall may contribute to atherogenesis¹⁹ (see Chap. 11).

Type 1 Diabetes Mellitus

In a typical population of 212 people with T1DM treated with conventional therapy, a 1% decrease in glycosylated hemoglobin was associated with an 8% decrease in triglycerides.²⁰ Ideal therapy of patients with T1DM includes multiple daily injections of insulin or the use of a continuous subcutaneous infusion of in-

sulin. Institution of such therapy lowers triglycerides with near normalization of glucose levels. Changes in LDL and HDL levels are more variable.

In the DCCT, intensive diabetes therapy was associated with a decrease in the incidence of retinopathy, nephropathy, and neuropathy. Intensive therapy was also associated with a decreased incidence of hypercholesterolemia, defined as an LDL cholesterol over 160 mg/dL.²¹ Triglyceride levels as well as LDL cholesterol levels were lower with intensive therapy, but HDL cholesterol did not increase.²² The intensive therapy group manifested other potentially beneficial lipoprotein changes including a decrease in IDL, small, dense LDL, and lipoprotein(a) [Lp(a)].²³ However, weight gain was more common in the intensive therapy group. Patients who experienced the most weight gain with intensive therapy also had more IDL, more dense LDL, and lower concentrations of HDL cholesterol, adverse lipoprotein changes that would be predicted to increase coronary artery risk.²⁴ These data suggest that intensive insulin therapy alone, at least with current technologies, does not optimally decrease the vascular risk associated with diabetic dyslipidemia in T1DM patients.

Type 2 Diabetes Mellitus

Evaluating the effects of glycemic control on plasma lipoproteins in patients with T2DM is difficult because of the heterogeneous therapeutic approaches to this disease. Substantial effects on dyslipidemia are usually seen when therapy is initiated, regardless of the type of therapy. In previously treated patients for whom new therapies are added, lipoprotein effects are more modest.

Weight loss (as little as 5 kg in some studies) achieved by diet and exercise improves dyslipidemia in patients with T2DM and impaired glucose tolerance.^{25,26} T2DM patients gain weight when either sulfonylurea or insulin therapy is initiated. Despite this weight gain, triglycerides decrease and HDL cholesterol increases as glucose levels fall. Acarbose, an α -glucosidase inhibitor that

lowers glucose by inhibiting carbohydrate metabolism in the intestine, has been shown to improve triglyceride metabolism.²⁷

There are currently two classes of insulin-sensitizing agents, biguanides and the thiazolidinediones. Both have favorable effects on dyslipidemia. These beneficial effects on lipoprotein metabolism may be greater than those seen with sulfonylurea therapy because both classes of drugs decrease insulin resistance and insulin concentrations in addition to lowering glucose.

Metformin, a biguanide, has been available for use in the United States since 1995. The molecular mechanism of action for this drug is unknown, but metformin is known to decrease hepatic glucose output, promote insulin-mediated glucose disposal, and decrease fatty acid oxidation, all reflecting improved insulin sensitivity. Metformin decreases triglycerides²⁸ and may increase HDL cholesterol. Unlike insulin, sulfonylureas, and thiazolidinediones, metformin causes these improvements in dyslipidemia without causing weight gain. Adipose mass may actually decrease in some patients.²⁹

Thiazolidinediones include troglitazone, rosiglitazone, and pioglitazone. These drugs are ligands for peroxisome proliferator-activated receptor (PPAR)- γ , a nuclear receptor that activates gene transcription, particularly in adipose tissue and macrophages. The most clinical data are available for troglitazone, although this drug was removed from the market in 2000. In insulin-treated patients, the addition of troglitazone has little effect on diabetic dyslipidemia.³⁰ When used as monotherapy even at low doses, troglitazone causes considerable decreases in triglyceride levels in T2DM but increases LDL levels.³¹ Fewer data are available for the other thiazolidinediones, but both compounds lower triglycerides in animals.^{32,33} One disadvantage of these compounds is that they can cause striking weight gain (see Chap. 32).

PATHOPHYSIOLOGY

The mechanisms underlying lipoprotein abnormalities in diabetes are complex. However, many of the same mechanisms contribute to metabolic profiles in both T1- and T2DM. In the simplest terms, dyslipidemia in diabetes is caused by the lack of appropriate insulin signaling. In untreated T1DM, the defect is caused by insulin deficiency. In T2DM, the defect is caused by the combination of relative insulin deficiency and the inability of the insulin receptor to transmit its signal appropriately.

Type 1 Diabetes Mellitus

Diabetic ketoacidosis usually causes mild to moderate hypertriglyceridemia. Decreased expression of the enzyme lipoprotein lipase (LPL) appears to be mainly responsible. LPL catalyzes the rate-limiting step in triglyceride metabolism.³⁴ LPL is made in multiple tissues, but the major sites of expression are cardiac muscle, adipose tissue, and skeletal muscle. The active enzyme is located at the capillary endothelium, where it hydrolyzes triglycerides of circulating lipoproteins. Fatty acids released by this process are available for uptake in muscle, where they are oxidized, and fat, where they are stored. Insulin is required for multiple steps of LPL expression including transcription, translation, and activation of the enzyme, which involves glycosylation of LPL and transport of the protein to heparan sulfate binding sites at the capillary endothelium. In the setting of ketoacidosis, LPL activity is very low, leading to hypertriglyceridemia. Triglyceride levels improve rapidly with institution of appropriate insulin therapy, but mild dyslipidemia can persist for months after a bout of ketoacidosis. In-

sulin rapidly activates available LPL in tissues, but restoration of all the levels of LPL regulation requires chronic insulin treatment.³⁵

Although the degree of hypertriglyceridemia in diabetic ketoacidosis (DKA) is usually moderate, severe dyslipidemia can occur rarely with triglycerides exceeding 20,000 mg/dL. In this setting, triglyceride elevations may complicate initial management³⁶ due to artifactual decreases in glucose and sodium.

Type 2 Diabetes Mellitus

T2DM is usually associated with obesity and insulin resistance. Insulin resistance has multiple effects on lipid metabolism (Fig. 47-2), many of which are also relevant to well-controlled patients with T1DM who may have gained weight due to intensive insulin therapy.

The hydrolysis of triglycerides in adipocytes is mediated by hormone-sensitive lipase (HSL). HSL activity is stimulated by catecholamines producing lipolysis and causing the release of fatty acids from adipocytes. In the absence of insulin resistance, HSL activity is exquisitely sensitive to suppression by insulin, and circulating fatty acid levels are low. In insulin resistance caused by obesity, insulin does not suppress HSL, lipolysis occurs unchecked, and fatty acid levels are elevated (step 1 in Fig. 47-2).

Fatty acids are reesterified into triglycerides in the liver. In the presence of newly synthesized lipid, microsomal transfer protein (MTP) stabilizes apoB and allows the generation of new VLDL particles. In the absence of MTP (as in the rare condition α -beta-lipoproteinemia), no VLDL is secreted from liver. Increased VLDL production driven in part by synthesis of new triglycerides from circulating fatty acids is probably the most important reason for dyslipidemia in T2DM (step 2 in Fig. 47-2). Inhibition of MTP activity is an attractive potential therapy for this condition.³⁷

Most individuals with T2DM and moderate hypertriglyceridemia have normal LPL activity (step 3 in Fig. 47-2). However, VLDL clearance tends to be decreased in these patients due to the expanded pool size of VLDL triglycerides. LPL at the capillary endothelium becomes saturated at triglyceride levels between 150 and 250 mg/dL. Above these levels, VLDL particles have prolonged circulating times that affect their interaction with HDL, resulting in triglyceride enrichment of HDL particles (see below).

In T2DM patients with marked hypertriglyceridemia, heterozygous LPL deficiency may be responsible for the phenotype. Most humans with heterozygous LPL deficiency have a mild phenotype, but severe hypertriglyceridemia (see below) can be observed when the increased VLDL production rates of T2DM are combined with the impaired VLDL clearance of LPL deficiency.³⁸ LPL deficiency among people with diabetes does not appear to be common.³⁹

IDLs are atherogenic and are increased in diabetes.⁴⁰ These particles are metabolized by hepatic lipase (HL; step 4 in Fig. 47-2) to LDL. HL activity is increased in T2DM⁴¹ and probably participates in the conversion of LDL to small, dense LDL.

The atherogenic particles IDL, LDL, and small, dense LDL have access to the subendothelial space of the vascular wall, where their presence contributes to the complicated evolution of atherosclerotic lesions (step 5 in Fig. 47-2). LPL, which hydrolyzes lipoproteins at the capillary endothelium, is also expressed by vessel wall macrophages, where it appears to promote atherosclerosis.^{42,43} Lipoproteins in the vessel wall are subject to oxidative modification that promotes their uptake by macrophages, leading to foam cell development. People with diabetes may be more likely to generate oxidized lipoproteins.⁴⁴ Oxidized lipoproteins may increase vessel wall matrix components such as proteoglycans.⁴⁵

FIGURE 47-2. Pathophysiology of diabetic dyslipidemia. The diagram reflects mechanisms in type 2 diabetes. Many of the same mechanisms are operative in patients with type 1 diabetes. In the setting of insulin resistance, hormone-sensitive lipase (HSL) causes the release of fatty acids from adipocytes (step 1). In normal physiology, HSL is suppressed by low concentrations of insulin. Fatty acids are cleared by the liver, where they are re-esterified to form triglycerides. The synthesis of lipid in liver is associated with the stabilization of apolipoprotein B (apoB), a process mediated by microsomal transfer protein (MTP). ApoB is the major apolipoprotein for very-low-density lipoproteins (VLDLs). The increased production of VLDL is a major cause of diabetic dyslipidemia (step 2). VLDLs are metabolized by lipoprotein lipase (LPL, step 3) to generate intermediate-density lipoproteins (IDLs). These particles are metabolized by hepatic lipase (HL) to generate low-density lipoproteins (LDLs; step 4). HL is also important for the generation of small, dense LDL. IDL, LDL, and small, dense LDL all have access to the subendothelial space of the artery wall, where they initiate a complex series of events (step 5). Reverse cholesterol transport can occur when cholesterol in the vessel wall is transferred to high-density lipoproteins (HDLs), in part through the action of ATP-binding cassette transporter 1 (ABC1; step 6). Cholesterol can be transferred to VLDLs (and other lipoproteins) through the action of cholesteryl ester transfer protein (CETP, step 7). VLDL is then cleared by hepatic receptors such as the LDL receptor (LDLR) and the LDL receptor-related protein (LRP; step 8). Cholesterol can also be transferred to the liver directly through the interaction of HDL with a scavenger receptor (SR-B1; step 9).

Vascular calcification is associated with accelerated mortality in diabetes, and diabetic dyslipidemia activates osteogenic gene expression in diabetic vasculature.⁴⁶ Oxidized lipoproteins appear to initiate an inflammatory cascade associated with the release of cytokines and the recruitment of new cells including smooth muscle cells.⁴⁷ Inflammatory markers such as high sensitivity C-reactive protein predict vascular risk.⁴⁸

The reverse cholesterol transport system utilizes HDL to move cholesterol from peripheral tissues such as the arterial wall to the liver for excretion. HDL levels are low and the composition of these particles is abnormal in diabetes, suggesting that reverse cholesterol transport is impaired. Recent discoveries of critical proteins involved in reverse cholesterol transport will help to clarify the role of this system in diabetic dyslipidemia.

The removal of cholesterol from tissues requires ATP-binding cassette transporter 1 (ABC1).⁴⁹ Mutations in ABC1 are responsible for Tangier disease, characterized by absence of HDL cholesterol. In the presence of ABC1, cholesterol is transferred to HDL

particles (step 6 in Fig. 47-2). HDL delivers cholesterol to the liver by two pathways, an indirect one and a direct one.

The indirect pathway is dependent on the interaction between HDL and triglyceride-rich particles such as VLDL. Cholesteryl ester transfer protein (CETP) moves esterified cholesterol from HDL to VLDL in exchange for triglyceride (step 7 in Fig. 47-2). This process is increased in diabetes.⁵⁰ Overexpression of CETP in mice increases experimental atherosclerosis.⁵¹ CETP produces VLDL particles that are enriched in cholesterol, making them more atherogenic. The process also produces triglyceride-enriched HDL particles, making them a better substrate for the elevated levels of hepatic lipase that ultimately metabolize HDL, leading to lower HDL levels.⁵² CETP also promotes the formation of small, dense LDL in diabetes. Cholesterol-enriched VLDL can be cleared by the low-density lipoprotein receptor (LDLR) and the LDLR-related protein (LRP) (step 8 in Fig. 47-2).

The direct pathway involves the interaction between HDL and scavenger receptor, class B, type I (SR-BI) (step 9 in Fig. 47-2).

SR-BI is involved in a process that is different from receptor-mediated endocytosis. This receptor binds HDL, the cholesteryl ester in HDL is selectively transferred to the liver, and then the lipid-depleted HDL is released from SR-BI. The receptor can also bind VLDL and LDL. SR-BI knockout mice (genetically modified animals with a mutation in SR-BI) have more experimental atherosclerosis,⁵³ whereas overexpression of SR-BI suppresses atherosclerosis.⁵⁴ The role of SR-BI in diabetic dyslipidemia is unknown.

T2DM may also be characterized by abnormalities of postprandial lipoprotein metabolism.⁵⁵ After a fatty meal, chylomicrons are generated by the intestine and rapidly metabolized to chylomicron remnants (similar in composition to IDL) that are cleared by the liver. However, current technologies do not allow the simple clinical evaluation of postprandial lipid metabolism.

TREATMENT

The Chylomicronemia Syndrome

Extreme elevations of triglycerides (usually >2000 mg/dL) can cause a discrete clinical syndrome due to the presence of high concentrations of chylomicrons.⁵⁶ The presentation can include pancreatitis, eruptive xanthomas, lipemia retinalis (the appearance of white arterioles and venules at fundoscopy), dyspnea, hepatosplenomegaly, and neurologic defects such as memory loss and carpal tunnel syndrome. Extreme hypertriglyceridemia does not uniformly cause the syndrome. People with uncontrolled diabetes are frequently seen in specialty clinics with documented chronic, extreme hypertriglyceridemia (between 2000 and 10,000 mg/dL) and no symptoms. The mechanisms underlying susceptibility to triglyceride-induced pancreatitis are unknown.

Most patients with the chylomicronemia syndrome have diabetes, but only a small percentage of people with diabetes develop this syndrome. People with diabetes and an underlying genetic hyperlipidemia are most likely to be affected. As noted above, the combination of heterozygous LPL deficiency and diabetes can cause the syndrome, but familial combined hyperlipidemia (FCH) is a more likely contributor. FCH, an autosomal dominant phenotype that might be influenced by several different genes,⁵⁷ is present in about 1-2% of Western populations. It is characterized by the overproduction of hepatic lipoproteins, exacerbating the accelerated VLDL production seen in diabetes. However, chylomicronemia is uncommon even in patients with diabetes and an underlying familial dyslipidemia. Additional factors are usually required. Common antecedents are obesity (which increases VLDL production by poorly defined mechanisms), ethanol, oral estrogens, hypothyroidism (which decreases LPL activity and decreases lipoprotein clearance), thiazide diuretics, β -adrenergic blocking agents (except those with intrinsic sympathomimetic activity), high doses of glucocorticoids, and retinoids.

In patients with no history of the chylomicronemia syndrome, appropriate therapies with potential for elevating triglycerides should not be withheld from diabetics with dyslipidemia. For example, beta blockers (despite their proclivity for raising triglycerides) decrease cardiovascular mortality in people with diabetes. It is prudent to measure serum lipids after instituting such therapy. In women with diabetes and hypertriglyceridemia, transdermal estrogen replacement therapy is preferred over oral estrogens because of the tendency for the latter to increase triglycerides further.

In patients with the chylomicronemia syndrome, conservative therapy for the routine management of pancreatitis is indicated. The cessation of oral intake, the use of intravenous hydration, and treatment of hyperglycemia with insulin usually result in striking decreases in triglycerides within days. Plasmapheresis has been used to treat this disorder.⁵⁸ This therapy does not normalize triglycerides, has not been shown to be superior to conservative therapy, alters intravascular volume in the setting of a disorder associated with severe volume shifts, and requires anticoagulation, which might carry additional risk in the patient with pancreatitis.

In those with recurrent triglyceride-induced pancreatitis who anticipate becoming pregnant (which exacerbates hypertriglyceridemia), total parenteral nutrition or low-fat diets supplemented with medium-chain triglycerides may decrease pancreatitis risk. Surgery is not usually recommended for recurrent triglyceride-induced pancreatitis. However, surgically induced fat malabsorption⁶⁰ has been used in severe cases with apparently good results.

Clinical Trials Supporting the Use of Lipid-Lowering Medications in Diabetes

Results of clinical trials designed to determine the effects of lipid lowering on cardiac endpoints in people with diabetes are in progress. *Post hoc* analyses of large trials that included subsets of diabetic subjects uniformly support the use of lipid lowering to decrease vascular risk in people with diabetes (Table 47-1).

The Scandinavian Simvastatin Survival Study (4S) randomized men and women with stable angina or a history of myocardial infarction to placebo or simvastatin, an HMG-CoA reductase inhibitor. The trial included 202 people with a clinical history of diabetes.⁶¹ Although data on these individuals are important, they may not be representative of the average person with diabetic dyslipidemia due to the lipid entry criteria of the trial. Participants had total cholesterol values between 212 and 309 mg/dL and triglyceride values <220 mg/dL.

The primary endpoint of the 4S trial was total mortality. There were several secondary endpoints including major coronary events and any atherosclerotic event. The risk of major coronary events was decreased by 55%, the risk of any atherosclerotic event was decreased by 37%, and there was a trend toward less total mortality in simvastatin-treated diabetics. There were an additional 281 patients in 4S with fasting glucose levels consistent with a diagnosis of diabetes, and 678 patients with impaired fasting glucose. An economic analysis of the trial using these larger subsets showed that simvastatin caused the greatest decrease in cardiovascular disease-related hospital days in people with diabetes.⁶²

The Cholesterol and Recurrent Events (CARE) Trial also used an HMG-CoA reductase inhibitor, pravastatin, in both men and women with known vascular disease. The trial included 586 diabetics with lower LDL cholesterol levels than those studied in 4S.⁶³ Lipid lowering in this diabetic subset decreased coronary events by 25%.

Gemfibrozil, a fibrate drug, was used in men with vascular disease and low levels of HDL in the Veterans Affairs HDL Intervention Trial (VA-HIT). There was no effect of drug treatment on LDL cholesterol levels, but HDL levels increased and triglyceride levels decreased. The trial included 630 diabetics, and there was a 24% decrease in death due to coronary heart disease or stroke in the members of this group randomized to gemfibrozil.⁶⁴

Several other trials, including one primary prevention trial,⁶⁵ have shown trends toward a reduction in cardiovascular risk with lipid lowering in people with diabetes.

TABLE 47-1. Summary of Important Lipid-Lowering Clinical Trials Including Patients with Diabetes

Trial	Medication	No. of Subjects with Diabetes	Baseline Lipid Values for Diabetics	Lipid Outcomes for Diabetics in the Treatment Group	Clinical Outcome Compared with the Placebo Group
Scandinavian Simvastatin Survival Study (4S)	Simvastatin (HMG-CoA reductase inhibitor)	202 men and women (plus additional 281 with undiagnosed diabetes at entry)	LDL: 176 mg/dL Triglycerides: 153 mg/dL HDL: 42 mg/dL	LDL decreased 36% Triglycerides decreased 11% HDL increased 7%	37% decrease in vascular events in diabetics. Trend favoring less total mortality in treated diabetics
Cholesterol After Recurrent Events (CARE)	Pravastatin (HMG-CoA reductase inhibitor)	586 men and women	LDL: 136 mg/dL Triglycerides: 164 mg/dL HDL: 38 mg/dL	LDL decreased 27% Triglycerides decreased 13% HDL increased 4%	25% decrease in coronary events in diabetics
Veterans Affairs HDL Intervention Trial (VA-HIT)	Gemfibrozil (fibric acid derivative)	630 men	LDL: 111 mg/dL Triglycerides: 161 mg/dL HDL: 32 mg/dL (for the entire study group)	LDL did not change Triglycerides decreased 31% HDL increased 6% (for all subjects treated with gemfibrozil)	24% decrease in death due to coronary heart disease or stroke in diabetics

Dyslipidemia Management

The results of UKPDS indicate that glycemic control has clear beneficial effects on microvascular disease but marginal effects on macrovascular disease.⁶⁶ One explanation is that some interventions lower glucose without affecting insulin resistance, a proatherogenic condition. Metformin-treated patients tend not to gain weight and have a reduction in insulin resistance as well as lower levels of triglycerides, making metformin a useful agent for glucose lowering in dyslipidemic T2DM patients with normal serum creatinine. In addition, a small subset in UKPDS had a reduction in cardiovascular endpoints.⁶⁷

Dyslipidemia frequently persists even with excellent glycemic control. Given the risk of coronary events in diabetics, including those with no history of vascular disease, treating dyslipidemia with medications should be considered in every person with diabetes soon after diagnosis, after glucose levels have stabilized.

Optimal lipid levels for adults with diabetes⁶⁸ include an LDL cholesterol <100 mg/dL, triglycerides <200 mg/dL, and HDL cholesterol levels >45 mg/dL. Many experts consider a normal triglyceride level to be <150 mg/dL since adverse compositional changes in LDL can be demonstrated above this level. It is useful to base lipid treatment decisions on fasting triglyceride levels.

Triglycerides >1000 mg/dL

The rare patient with triglycerides >1000 mg/dL is at risk for pancreatitis. Marked restriction of dietary fat to <10% of caloric intake is required. Insulin is recommended instead of oral hypoglycemic agents to lower glucose levels in these patients. Fibric acid derivatives such as gemfibrozil (600 mg twice a day taken 30 minutes before meals) or fenofibrate (160 mg once a day with meals) are indicated. Substantial lowering of triglycerides is unlikely without weight loss. For many, the goal is to maintain fasting triglycerides below 1000 mg/dL to decrease the risk of pancreatitis. The use of fish oil capsules (containing *n*-3 polyunsaturated fatty acids) can also be helpful. Fish oil (supplied as 1 g capsules containing at least 300-500 mg of docosahexanoic acid and eicosapentanoic acid) should be administered as 1 capsule twice a day

with food and gradually increased to a total of 6-10 capsules a day. Gastrointestinal side effects are common.

Triglycerides 400-1000 mg/dL

A minority of people with diabetes have fasting triglycerides at this level. Since triglyceride levels are inversely related to HDL cholesterol levels, HDL levels may be very low in these patients.

Diet (see Chap. 26) and exercise counseling are indicated for every person with diabetes. Exercise is generally required for sustained weight loss. It improves dyslipidemia and is known to increase the expression of LPL in human muscle.⁶⁹ A graded exercise test is appropriate for sedentary diabetics over the age of 35 before beginning an exercise program. Lower extremity protective sensation should be assessed and non-weight-bearing exercises such as cycling, rowing, or swimming recommended for those with sensory defects. A reasonable goal is 30 minutes of moderate physical activity on most days of the week; on average, 150 minutes a week is recommended. Referral to an exercise physiologist may be helpful, but the physician providing individualized recommendations may enhance compliance. It may be helpful to keep a record of physical activity analogous to recording home blood glucose results.

Fibrates (gemfibrozil or fenofibrate; see above for doses) are appropriate for these patients. These drugs are ligands for the nuclear hormone receptor PPAR α .⁷⁰ Activation of this receptor increases fatty acid oxidation, leading to decreased hepatic lipogenesis and decreased VLDL secretion. This receptor also increases LPL activity, which clears VLDL particles and promotes the generation of HDL particles. Fibrates lower triglycerides, increase HDL cholesterol, and increase the buoyancy of LDL particles. LDL cholesterol may increase modestly with fibric acid therapy. Fenofibrate may be preferred since it is administered once a day and the drug may be more likely than other fibrates to lower LDL cholesterol. These agents increase the lithogenicity of bile and should be used cautiously in patients with gallstones. Gastrointestinal side effects and erectile dysfunction can occur. The drugs displace warfarin from its binding sites; clotting parameters must be monitored

closely, and most patients will require a reduction in warfarin dose. Hepatic dysfunction and myositis can occur, especially when fibrates are used in combination with other lipid-lowering agents.

In the patient already being treated with insulin, extended release niacin is an alternative. Niacin appears to work by decreasing the release of fatty acids from adipocytes (see step 1 in Fig. 47-2), thereby decreasing hepatic lipogenesis and VLDL synthesis. It is the most potent agent for increasing HDL cholesterol. Niacin increases glucose, which can be treated by increasing the insulin dose. In many obese dyslipidemic patients, the effect on glucose metabolism may be small. Flushing is common but not serious for most patients. It can be minimized by taking enteric-coated aspirin before each dose and by avoiding alcohol, spicy foods, and hot beverages. More serious side effects include macular edema (which is rare), hyperuricemia, hepatitis, and myositis. A once-nightly extended-release form of niacin (Niaspan™) appears to be tolerated well. Doses should be gradually increased to 1500–2000 mg a day at bedtime.

Triglycerides 200–400 mg/dL

Many people with T2DM will have levels in this range. Triglycerides at this level are associated with an increase in IDL, more small, dense LDL, and low HDL. Statin drugs (HMG-CoA reductase inhibitors) are the drugs of choice for this group. These drugs inhibit the synthesis of cholesterol, causing the induction of LDL receptors in the liver. Hence, LDL clearance is enhanced. At higher doses, all statins also lower triglycerides. The mechanism may be a combination of enhanced clearance of VLDL particles through the LDL receptor and inhibition of VLDL secretion. Statins also elevate HDL levels.

Diabetics are unlikely to reach therapeutic goals on the standard starting doses of statins. Simvastatin at 40 mg (given with food in the evening), atorvastatin 20 mg (given with food in the evening), and pravastatin 40 mg (taken at bedtime on an empty stomach) may be effective. Patients may complain of sleep disturbances or difficulty concentrating with some statins; pravastatin does not penetrate the central nervous system and may be an option for these individuals.⁷¹ Muscle aches with completely normal muscle enzymes (CPK and aldolase) are common with statin use. The etiology of this effect is unknown. Some patients improve when a different statin drug is used.

Liver dysfunction occurs in <1% of patients who use statins. Myositis is rare. The risk for these side effects increases with concomitant use of erythromycin, cyclosporine, antifungal agents, and protease inhibitors used to treat HIV infection. The risk is also increased in patients treated with statins in addition to other lipid-lowering medications such as fibrates or niacin.

Patients with dyslipidemia and established coronary heart disease are at high risk for subsequent vascular events. Many experts use combinations of lipid-lowering drugs to reach therapeutic goals. Fenofibrate at 160 mg in the morning and simvastatin or pravastatin at 20 mg in the evening can have beneficial effects on multiple lipid parameters in patients with diabetic dyslipidemia. The combination of a statin with niacin may be considered in the patient at very high risk for coronary events who is taking insulin for glucose control. With combination therapy, liver function tests should be followed regularly, and patients should be warned about the symptoms of myositis and hepatitis. Combination therapy should not be used in patients with significant renal dysfunction or in those taking cyclosporine.

Triglycerides <200 mg/dL with LDL cholesterol >100 mg/dL

Statins are the drugs of choice in this group. Bile acid sequestrants are available, but they can increase triglyceride levels, are not as potent as statins for lowering cholesterol, and are not tolerated as well as statins. In addition to statins, it may be appropriate to treat patients in this group, as well as diabetics with higher lipid levels, with fish oils (n-3 polyunsaturated fatty acids). The GISSI-Prevenzione trial showed that low-dose fish oil supplementation (1 g daily) decreased the risk of subsequent cardiovascular events in people with a history of recent myocardial infarction.⁷² This trial included 405 diabetics treated with fish oil and 426 diabetics treated with placebo.

Summary of Treatment Recommendations

Diabetics are at high risk for atherosclerotic complications. Treating dyslipidemia may decrease the risk of these complications. Every person with diabetes should receive dietary advice and exercise counseling. Many should also receive a lipid-lowering medication, usually a statin. Lipid management is part of a comprehensive approach to treating vascular risk that should also include counseling for smoking cessation, aspirin therapy, optimal blood pressure control, and consideration of need for an angiotensin-converting enzyme inhibitor.

Hypertension and Diabetes

Norman M. Kaplan

Hypertension and diabetes frequently coexist, in large part from underlying obesity. Hypertension is found in over 70% of all diabetic patients,¹ and the risk for developing diabetes is almost doubled by the presence of hypertension even among nonobese people with blood pressure >130/85 mm Hg.² When the two coexist, cardiovascular and renal complications occur at a much higher rate, at least twofold more frequently overall, and progressive nephropathy is many times more frequent.

There may be a potential explanation for some of the increased prevalence of hypertension, nephropathy, and diabetes: Hyperglycemia during pregnancy reduces nephrogenesis in the fetus.³ Just as maternal protein deprivation leads to a reduced number of nephrons, so could hyperglycemia. The infants of women with abnormal glucose tolerance or overt diabetes would then be susceptible to more hypertension, diabetes, and nephropathy.

Beyond the possible contribution to impaired fetal development, there are a number of other reasons for the increasing prevalence of diabetes and hypertension. These include:

- Increasing age of the population
- Rapid growth of more susceptible populations including Hispanic Americans and African-Americans
- Prolonged survival of those with type 1 diabetes
- Expanding reach of medical care
- Increasing prevalence of obesity due to decreased physical activity and increased caloric intake

THE PREDOMINANT ROLE OF OBESITY

The current U.S. population is likely the fattest of all time. Obesity, defined as a body mass index (BMI) >30 kg/m², increased from 12% of U.S. adults in 1991 to 17.9% in 1998.⁴ The increase occurred in virtually every segment of the population, among both men and women, in teenagers to the elderly, and in all races and socioeconomic strata.

With increasing BMI, the rate of type 2 diabetes mellitus (T2DM) increases markedly. A 5-kg weight gain doubles the risk for diabetes, and the risk further increases with increased duration of being overweight.⁵ Not surprisingly, cardiovascular mortality is increased with increasing BMI, with about 300,000 annual deaths attributable to the consequences of obesity in the United States.⁶

The problem often begins in early childhood, when increased weight is associated with hyperinsulinemia, increased blood pressure, and dyslipidemia, particularly in those with greater central (visceral or abdominal) obesity.⁷

Prevention of weight gain in adults is difficult; it may be easier in children if they can be kept physically active, perhaps by turning off the TV and the computer.⁸ The clinician should devote greater attention to those who are both diabetic and hypertensive: In a European survey, only about 11% of type 1 diabetics had their hypertension adequately controlled.⁹ Moreover, with tighter control of both type 1 diabetes mellitus (T1DM) and T2DM, the associated weight gain may result in an increase in both blood pressure and dyslipidemia.¹⁰

INCREASING RECOGNITION OF THE PROBLEM

All three recently published guidelines have emphasized the need for both earlier intervention at even lower levels of blood pressure for hypertensives with diabetes, and for more intensive therapy:

- The JNC-6 places all diabetic patients in the highest risk category (group C), wherein immediate drug therapy is indicated if blood pressure is above 130/85 mm Hg.¹¹
- The WHO-ISH places all diabetic patients with blood pressure above 140/90 mm Hg into risk group III (high risk), with a 15-20% risk of a major cardiovascular event over the next 10 years; those with blood pressure above 180/110 mm Hg are in risk group IV (very high risk), with a greater than 30% risk over 10 years.¹² Drug therapy is recommended immediately for both groups.
- The British Hypertension Society provides more specific risk assessment and recommends that drug treatment be started at 140/90 mm Hg with a target of below 140/80 mm Hg.¹³

ASSESSMENT OF BLOOD PRESSURE

Before therapy is begun, the presence and degree of blood pressure elevation must be carefully ascertained. Such an assessment should include out-of-the-office readings.

Out-of-Office Measurements

As with all patients, out-of-the-office measurements are needed both to establish the diagnosis and to monitor the management. White-coat hypertension is common, particularly among young type 1 diabetics, and if not recognized, may lead to misdiagnosis.¹⁴

Ambulatory blood pressure monitoring (ABPM) is best, but it most likely will remain unavailable, because third-party payers often do not reimburse for the procedure. With ABPM, the common

lack of a nocturnal drop in pressure in diabetics can be recognized and should lead to more intensive control of the blood pressure.¹⁴

Recognition of Postural Hypotension

All diabetics, particularly if over age 60, should have their blood pressure measured supine and standing, since postural and postprandial hypotension is common and potentially hazardous. In a study of 204 type 2 diabetic subjects (average age, 58), postural hypotension was found in 28.4% and postural dizziness in 22.5%.¹⁵ If present, postural and postprandial hypotension must be managed before supine and seated hypertension is treated.¹⁶

NONPHARMACOLOGIC THERAPY

Therapy for all hypertension should begin and continue with lifestyle modifications, even more so in the typically obese type 2 diabetic. Despite the obvious attraction of lifestyle changes, they are hard to accomplish and may not be as protective as drug therapy. The high risk of even diet-controllable T2DM almost mandates early and intensive antihypertensive drug therapy.

Weight Loss

Weight loss lowers blood pressure at least in part by improving insulin sensitivity.¹⁷

Exercise

Those who are sedentary and unfit may develop more diabetes whether lean or obese. Walking alone, without more vigorous activity, reduces the risk for diabetes and will lower blood pressure.¹⁸

The manner by which exercise helps both diabetes and hypertension goes beyond a decrease in body weight. Exercise increases glucose uptake into skeletal muscles, making them more insulin sensitive. The effect was seen in mice without muscle insulin receptors, suggesting a phenomenon mediated by nonmuscle cells or by downstream signaling events.¹⁹

The benefits of exercise in patients with diabetes include improvement in glycemic control, lowering of blood pressure, reduction in levels of triglyceride-rich VLDL, probable improvement in fibrinolytic activity, and reduction in cardiovascular disease.

Moderate Sodium Reduction

Moderate sodium reduction is safe and can be effective,²⁰ perhaps even more in those diabetics whose hypertension is related to volume expansion from the renal impairment of nephropathy. Moreover, the antiproteinuric effect of ACE inhibitors is markedly enhanced by a lower sodium intake.²¹ But even without nephropathy, diabetic subjects need to reduce their sodium intake since insulin-resistant subjects have an impaired natriuretic response to high sodium intake.²²

The value of moderate sodium reduction is illustrated by a study in 34 type 2 diabetic hypertensive patients. A reduction of sodium intake of 60 mmol/d for 3 months was associated with a 20-mm Hg fall in systolic pressure; when sodium intake was increased, the blood pressure rose 11 mm Hg.²³

Moderate Alcohol Consumption

Diabetic subjects have been reported to obtain a protective effect against coronary disease by regular, moderate alcohol consumption (no more than 2 drinks a day) similar to that seen in several other groups²⁴ (Fig. 48-1). In addition to other mechanisms for cardio-

FIGURE 48-1. Survival curves for coronary heart disease mortality over 13 years according to alcohol intake in 983 older-onset diabetic persons in the Wisconsin Epidemiologic Study of Diabetic Retinopathy. (Reprinted with permission from Valmadrid et al.²⁴).

protection provided by alcohol, insulin sensitivity is improved.²⁵ The risk of T2DM was reduced by 42% among middle-aged Japanese men who drank moderately.²⁶

The type of alcoholic beverage is most likely irrelevant. Wine drinkers have the lowest risk for coronary disease, perhaps because of their healthier lifestyle; red wine drinkers have no greater protection than white wine drinkers.²⁷

Cessation of Smoking

As the most important lifestyle issue to be addressed, smoking may markedly aggravate insulin resistance in type 2 diabetics.²⁸

Others

Dietary Fiber

In a large population of young, healthy subjects, increased dietary fiber intake was associated with lower body weight, lower waist-to-hip ratio, lower fasting insulin, lower blood pressure, and better lipid profiles.²⁹

Dietary Magnesium

Low serum magnesium, but not low dietary magnesium intake, was a strong independent predictor of severity in type 2 diabetics in over 12,000 middle-aged people.³⁰

ANTIHYPERTENSIVE DRUG THERAPY

The best documentation of the need to lower diastolic blood pressure to 80 mm Hg or below comes from the Hypertension Optimal Treatment (HOT) trial.³¹ Among the 19,000 participants in the trial, the only significant benefit to reducing the diastolic blood pressure to near 80 mm Hg was seen among the 1501 diabetic hypertensive subjects. They achieved a greater than 50% reduction in major cardiovascular events (Fig. 48-2). As in the HOT trial, to achieve the necessary goal of blood pressure <130/80 mm Hg usually requires two or more antihypertensive drugs.

In the population of 3642 type 2 diabetics screened for the United Kingdom Prospective Diabetes Study (UKPDS) but not entered into the trial, the progressive reduction in major cardiovascular events seen with progressive reduction of systolic blood pressure from over 160 mm Hg to 110 mm Hg was accomplished by various antihypertensive drugs.³²

To provide the other essential corrections for concomitant factors, multiple nondrug and drug therapies will be needed. The benefits of such intensive therapy are impressive.³³ In this trial, diabetic subjects were randomly assigned to standard or more intensive therapy, the latter requiring a blood pressure below 140/90 mm Hg, HbA_{1c} below 6.5%, total cholesterol below 5 mmol/L, and the use of ACE inhibitors and aspirin plus multiple lifestyle modifications. At the end of 3.8 years of follow-up, those on intensive therapy achieved major benefits (Fig. 48-3). Such intensive therapy, though costly, would not only reduce morbidity and mortality, but also lower lifetime medical costs.³⁴

Antihypertensive Drugs

For those diabetic hypertensive patients without proteinuria, a low-dose diuretic may be the appropriate first choice with an angiotensin-converting enzyme (ACE) inhibitor as a second drug and a long-acting calcium channel blocker (CCB) as third. Beta-blockers, and to a lesser extent alpha-blockers, may also be indicated. Rarely, central α_2 agonists may be useful. For those with proteinuria, an ACE inhibitor is mandatory (see Chap. 43). If an angiotensin II receptor blocker (ARB) should be substituted, it precludes use of an ACE inhibitor.

Diuretics

Low doses of diuretics (e.g., 12.5 mg of hydrochlorothiazide) are effective and safe in diabetic patients, as shown in the Systolic Hypertension in the Elderly Program (SHEP) trial.³⁵ A thiazide diuretic should be almost always included in the regimen and loop diuretics given only to those with serum creatinine above 1.5 mg/dL.

Beta-Blockers

Despite many warnings about their potential to aggravate diabetes in various ways, beta-blockers may be effective and safe.³⁶ They are mandatory for those who survive a myocardial infarction. Since they tended to be more protective than ACE inhibitors in the UKPDS trial³⁷ (Fig. 48-4), their use may increase.

Alpha-Blockers

In addition to their ability to relieve prostatism, alpha-blockers are better than any other class for reducing insulin resistance and improving dyslipidemia.³⁸

FIGURE 48-2. The risk for major cardiovascular events in the 1501 diabetic patients in the HOT study according to the target diastolic blood pressure level. (Adapted with permission from Hansson et al.³¹)

FIGURE 48-3. The development or progression of microvascular complications in the 80 diabetic hypertensives assigned to standard treatment compared to the 80 patients assigned to intensive treatment. (Reprinted with permission from Gaede et al.³³)

Calcium Channel Blockers

Concerns persist about the safety of CCBs, particularly the dihydropyridines (DHPs), and particularly in diabetic hypertensive subjects. In their recent review, Abernethy and Schwartz³⁹ state: "At present, in view of the greater evidence of a benefit of angiotensin-converting-enzyme inhibitors and beta-blockers in patients who have hypertension and diabetes,³⁷ the relative paucity of data on calcium antagonists in these patients, and the recent finding that the risk of a vascular event may be increased during calcium-antagonist treatment in such patients,^{40,41} calcium antagonists cannot be considered as first-line therapy for these patients."

As to their putative effect to increase coronary disease, the problem remains unique to large doses of short-acting agents and does not apply to long-acting agents. The safety of long-acting CCBs in patients with coronary disease was further documented in a 1-year follow-up of over 51,000 patients who were prescribed one of these agents after surviving an acute myocardial infarction.⁴²

FIGURE 48-4. Kaplan-Meier plots of proportions of patients who died of diseases related to diabetes (myocardial infarction, sudden cardiac death, stroke, renal failure) in the less tightly controlled group and the more tightly controlled groups based on use of either captopril or atenolol. (Reprinted with permission from the UKPDS Study Group.³⁷)

Their relative likelihood of 1-year mortality was no different than those not prescribed a long-acting CCB.

As to their particular effects in diabetes, most of the current evidence of a benefit from antihypertensive therapy in patients with diabetes comes from trials using DHP-CCBs⁴³ (Table 48-1).

In both the ABCD trial⁴¹ and the FACET study,⁴⁴ those diabetic patients given an ACE inhibitor had fewer cardiovascular events than those given a DHP-CCB, although the rates in those on CCBs were not increased beyond the expected numbers in those on no therapy. These results prompted Pahor and associates⁴⁵ to state that DHP-CCBs should not be used in diabetic hypertensives.

Birkenhager and Staessen⁴³ defend the use of DHP-CCBs thusly:

- The excellent protection found in Syst-Eur with nitrendipine was even better than that found in a similar group of hypertensive diabetics given a diuretic in the SHEP trial⁴⁶ (Fig. 48-5). The comparability of the two groups of diabetic hypertensive patients is shown by the similar rates of various cardiovascular events in the placebo groups of each study, shown on the right. Of those who were treated, the nitrendipine-based regimen in Syst-Eur provided even better protection than did the chlorthalidone-based regimen in SHEP.
- The major reduction in cardiovascular events in the 1501 diabetic subjects given felodipine-based therapy in the HOT trial³² (see Fig. 48-2).
- The presumed lack of significant adverse effects in the amlodipine quarter of the ongoing ALLHAT trial, with over 15,000 diabetic patients enrolled, since the Safety Monitoring Committee has not called for a discontinuation of the DHP-CCB limb of the trial, now in its fourth year.
- Multiple defects in both the ABCD and FACET studies, which included protocol breaks, crossovers, and imbalances of other therapies.

Additional evidence in defense of the benefits of CCBs for treatment of hypertensive diabetics comes from the results of the 719 diabetics among the 6614 elderly hypertensives in the Swedish Trial of Old Persons with Hypertension-2 Study (STOP-2), the only completed trial that compared drugs from the three major classes: diuretics/beta-blockers, ACE inhibitors, and CCBs.^{46a} A lower rate of CHD and CHF was seen in those taking an ACE inhibitor, but there was a lower rate of stroke and mortality in those on a CCB.

The data now available provide no clear evidence that one class of drug is superior, although CCB-based therapy has been associated with fewer events than either diuretic- or ACE inhibitor-based therapy.

At present, the bottom line seems to be that either DHP-CCBs or non-DHP-CCBs are frequently needed to control hypertension in

TABLE 48-1. Rates of Events per 1000 Patients in the Seven Comparative Trials in Diabetic Hypertensives

	No. Pts.	Total Events per 1000 Patients			
		CHD	CHF	Stroke	Mortality
Diuretic and/or β -Blocker	1903	75	27	62	125
ACE I	1368	87	32	66	121
CCB	1657	71	32	53	83

FIGURE 48-5. Outcomes in the diabetic hypertensives enrolled in the Systolic Hypertension in the Elderly Program (SHEP) or the Syst-Eur trial. The two right-hand columns show the number of events per 1000 patient-years in the placebo groups in the two trials. The bars indicate the 95% confidence intervals. The numbers above the bars indicate the benefit of active treatments compared to placebo. (Reprinted with permission from Tuomilehto et al.⁴⁶)

most diabetics, particularly to prevent the progression of renal damage. They may be renoprotective even if they do not reduce proteinuria. In a 42-month follow-up of 48 proteinuric diabetics, the half given a DHP-CCB, nisoldipine, had no reduction in proteinuria, but a smaller fall in GFR than did the half given an ACE inhibitor.⁴⁷

Angiotensin-Converting Enzyme Inhibitors

An ACE inhibitor should always be used for those patients with proteinuria. This should most likely be expanded to normotensive diabetics with microalbuminuria; over 4 years, 9 of 23 such patients on placebo advanced in diabetic nephropathy, whereas only 2 of 21 given captopril advanced.⁴⁸

Whether an ACE inhibitor should also be the drug of first choice for all diabetic subjects without microalbuminuria is less certain, but this is looking more and more likely. In the Captopril Prevention Project (CAPPP), those diabetic patients given captopril had fewer events than did those given diuretics and beta-blockers, whereas there was no difference in the nondiabetics.⁴⁹ On the other hand, the ACE inhibitor was somewhat less protective than the beta-blocker in the UKPDS trial, the largest and longest trial involving type 2 diabetic hypertensives³⁷ (Fig. 48-4).

The renin-angiotensin system may be set inappropriately high in type 2 diabetics and it also may be less suppressed by high sodium intake,⁵⁰ so this could be a theoretical reason to use ACE inhibitors. Certainly ACE inhibitors have been found to be protective in diabetic patients who have survived a myocardial infarction.⁵¹ In the Heart Outcomes Prevention Evaluation (HOPE) trial, the 9297 patients with known cardiovascular disease included 38% with diabetes; over the 4–6 year follow-up, a 17% risk reduction for diabetic complications was reported for those given the ACE inhibitor ramipril compared to those assigned to placebo.⁵²

A Markov model simulating the progression of diabetic nephropathy was applied to patients 50 years of age with newly diagnosed T2DM.⁵³ The analysis found that treating all patients with an ACE inhibitor at a yearly cost of \$320 was about \$15,000 per patient more expensive than screening for microalbuminuria and then treating with an ACE inhibitor. ACE inhibitor treatment was, however, associated with increased quality-adjusted life expectancy at a cost:effectiveness ratio of \$7500 per quality-adjusted life-year gained.

As attractive as they are, ACE inhibitors may cause problems. They interfere with useful actions of angiotensin II such as vasodilator responses in skeletal muscle arterioles,⁵⁴ increase the risk of hypoglycemia,⁵⁵ and may worsen renal function in patients with diabetic nephropathy.⁵⁶ On the other hand, the ACE inhibitor-induced cough, the most common side effect, may protect against aspiration in elderly people with a poor cough reflex, diminishing their incidence of pneumonia.⁵⁷

Angiotensin II Receptor Blockers

For the 10% of patients given an ACE inhibitor who develop cough, an ARB is a logical alternative. Their more widespread usage is not recommended in any of the three recent guidelines,^{11–13} but they are being widely promoted for initial therapy.

These agents are in many ways similar to ACE inhibitors, but the renin-angiotensin system has three features that may give rise to differences in the benefits of ARBs versus ACE inhibitors⁵⁸ (Fig. 48-6):

1. **Non-ACE alternative pathways** for generation of angiotensin II have been recognized. In particular, the chymotrypsin-like serine protease chymase has been found in heart tissue and shown to have the ability to convert angiotensin I to angiotensin II, even in the presence of natural protease inhibitors.⁵⁹
2. **Beneficial effects of the increased levels of bradykinin** that accompany ACE inhibitors, but not ARBs, have been observed. These include adding to the antihypertensive effect of ACE inhibitors,⁶⁰ providing an important source of vasodilation that is NO-mediated. In a rat hypertensive model, enhanced vascular ACE activity was found to induce endothelial dysfunction by impairing the bioavailability of endothelium-derived NO. Both increased angiotensin II formation and decreased bradykinin levels were thought to be at work.⁶¹ ACE inhibitors also inhibit vascular smooth muscle cell growth.⁶²
3. **Activation of the angiotensin II receptors.** Most of the adverse effects of the renin-angiotensin system are mediated through the angiotensin I receptors, but increasing evidence supports beneficial effects mediated through the angiotensin II receptor, as shown in Fig. 48-6. Initial concerns that the increased levels of angiotensin II that circulate when the

FIGURE 48-6. The renin-angiotensin system with the sites of action of ACE inhibition and angiotensin I receptor blockade.

angiotensin I receptor is blocked could induce deleterious effects have been largely obviated by evidence that angiotensin II receptor stimulation is likely beneficial. For example, overexpression of the angiotensin II receptor activates the vascular kinin system and causes vasodilation.⁶³

Clinical Effects of ARBs

The many ARBs now available seem equipotent and equally free of side effects, although angioedema has been noted.⁶⁴ Losartan appears to be unique in having a modest uricosuric effect.⁶⁵

ARBs reverse left ventricular hypertrophy⁶⁶ and diminish proteinuria.⁶⁷ The only published outcome study comparing an ARB against an ACE inhibitor (ELITE I) suggested a better effect of losartan than captopril on heart failure.⁶⁸ However, the larger follow-up trial (ELITE II) was reported to show no difference.⁶⁹ The apparent failure to confirm the preliminary evidence of a better outcome with losartan than captopril removes the only current evidence for a meaningful difference between ACE inhibitors and ARBs. Another comparative trial in CHF patients, the Randomized Evaluation of Strategies for Left Ventricular Dysfunction (RESOLVD) study found no significant differences between the ARB candesartan and the ACE inhibitor enalapril.⁷⁰ The combination of the two was more beneficial in preventing left ventricular remodeling than either alone, whereas there was a trend toward fewer events with enalapril alone (which led to premature termination of the trial).

The Potential for Additive Effects

Since the two classes have different effects on various parts of the renin-angiotensin system, an additive effect may occur. Preliminary evidence has been reported for additive effects of the combination of low doses of lisinopril and losartan on blood pressure.⁷¹

OTHER DRUGS FOR HYPERTENSIVE DIABETIC SUBJECTS

Antidiabetic Agents

In addition to chronic effects, hyperglycemia will acutely raise blood pressure, probably by activating the renin system.⁷² As noted elsewhere, to achieve adequate glycemic control, most patients will require multiple therapies. There may be special vasodilatory effects of glitazones mediated through increased NO synthesis.⁷³ Any therapy that improves insulin sensitivity or lowers insulinemia should have long-term vascular protective effects.

Statins

The 483 diabetic patients in the Scandinavian Simvastatin Survival Study had as much benefit as the remainder of the subjects.⁷⁴ Even though statins may not improve insulin sensitivity, they have vasodilatory effects that may be additive to those provided by ACE inhibitors.⁷⁵

Estrogen Replacement Therapy

At least in Britain, fewer diabetic women were prescribed ERT than nondiabetic women. In a smaller number of obese type 2 diabetics, ERT (with medroxyprogesterone) was associated with reductions in waist circumference, HbA_{1c}, and cholesterol levels.⁷⁶ However, no data exist to support a cardiovascular protective effect of ERT in postmenopausal women with diabetes.

Aspirin

In the HOT trial³² aspirin (75 mg/d) reduced major cardiovascular events by 15%, all myocardial events by 36%, and had no effect on stroke. There were more bleeding episodes in the aspirin group, but no more fatal bleeding.

CONCLUSION

Hypertension and diabetes commonly coexist and pose a serious threat. Fortunately, significant protection can be provided, but the benefits may be hard to achieve. Clinicians must be more vigorous in applying more intensive therapy to this rapidly expanding, highly vulnerable population.

Heart Disease in Patients with Diabetes

Lawrence H. Young

Deborah A. Chyun

INTRODUCTION

Cardiovascular disease (CVD) is the leading cause of mortality and a major cause of morbidity in patients with diabetes mellitus. CVD results in large part from macrovascular coronary artery disease (CAD) and hypertension. The most common manifestations of CVD are angina, acute myocardial infarction (MI), heart failure, and sudden death.

Coronary artery atherosclerosis is extremely common in patients with type 2 diabetes mellitus (T2DM) and in patients with long-standing type 1 diabetes mellitus (T1DM). At an early stage, minor atherosclerosis is the nidus for further plaque buildup and the substrate for plaque rupture leading to acute coronary syndromes (unstable angina and acute MI). More advanced atherosclerosis significantly narrows the vessel lumen and restricts blood flow, leading to ischemia during exercise or emotional stress. Ischemia is sometimes associated with angina or dyspnea, but in some diabetic patients may be asymptomatic and therefore may not be detected by either the patient or physician. The first manifestation of CAD in such patients may be acute MI, heart failure, or sudden cardiac death.

CVD in diabetic patients is not restricted simply to the manifestations of CAD. The majority of individuals with T2DM have hypertension, which has an important role in the development of left ventricular dysfunction, heart failure, and atrial fibrillation, as well as being a risk factor for CAD. In addition, patients with diabetes often have impaired endothelial function, a tendency toward thrombosis, and abnormalities in left ventricular function which adversely influence the clinical course of their heart disease once it develops.

CORONARY ARTERY DISEASE

Epidemiology

Patients with both T1DM and T2DM are known to be at risk for the development of CVD. In the Framingham study the age-adjusted risk of CVD was 2–3 times greater in those with diabetes, primarily type 2 patients.¹ The average annual incidence of CVD was 39/1000 in men with diabetes versus 19/1000 in those without diabetes. In women with diabetes, the incidence was 27/1000 as compared to only 10/1000 in women without diabetes. In the recent United Kingdom Prospective Diabetes Study (UKPDS), there was a substantial risk of MI (17/1000 patient-years), stroke (5/1000 pa-

tient-years), angina (7/1000 patient-years) and heart failure (4/1000 patient-years) in conventionally treated T2DM patients.²

CVD is also a major cause of death in T1DM, often affecting patients during their fourth and fifth decades of life. In the Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR), CVD was responsible for 30% of the deaths in type 1 patients, with the vast majority attributable to CAD.³ In the Diabetes Control and Complications Trial (DCCT), the risk of cardiac events was 3/1000 patient-years in conventionally treated patients.⁴ Diabetes increases the risk of heart disease in all patients, but has a particularly adverse effect in women. In premenopausal women, CAD is extremely unusual except in women with diabetes. In the Nurses' Health Study, women with diabetes diagnosed before the age of 30 had a 12-fold increase in their risk of MI and fatal CAD.⁵

Etiology

The mechanisms responsible for macrovascular CAD in patients with diabetes are complex. Some of the risk for accelerated atherosclerosis in patients with T2DM can be attributed to the presence of multiple known cardiac risk factors, including hypertension, lipid abnormalities, and obesity.⁶ These risk factors are also associated with the insulin resistance syndrome and often precede the onset of T2DM. This has led to the "common soil" hypothesis, which postulates that similar genetic and environmental factors predispose both to the development of diabetes and CAD.⁷ Strategies to define the genes responsible for insulin resistance are currently underway.⁸ In addition to traditional risk factors, microalbuminuria^{9,10} and elevation of blood homocysteine levels^{11,12} appear to be significant risk factors for CVD in patients with diabetes.

Lipid abnormalities (see Chap. 47) are important contributors to the development of CAD, especially in T2DM. Insulin resistance and T2DM are often associated with reduced high-density lipoprotein (HDL) and increased triglyceride (TG) levels (see Chap. 47).¹³ Although elevations in low-density lipoprotein (LDL) cholesterol are not specifically related to diabetes, increased atherogenicity may be related to the presence of oxidized and small dense LDL particles (see Chap. 47).¹⁴ Alterations in lipids are more pronounced in women than in men with T2DM and are associated with more central adiposity, hypertension, and higher fibrinogen levels.^{15,16}

Hemostatic abnormalities have a role both in the atherogenic process and in promoting thrombosis once CAD is established. Alterations in factor VIII, von Willebrand factor, plasminogen

activator inhibitor, and platelet function are all associated with CAD in patients with diabetes.¹⁷⁻¹⁹ Lipid peroxidation may cause oxidative stress and contribute to increased platelet activation in patients with diabetes.¹⁸ Thus abnormalities in platelet function, thrombosis, and fibrinolysis likely contribute to the increased risk of CAD in patients with diabetes.

Inflammation is also thought to be an important mechanism in the development of atherosclerosis. A number of inflammatory markers are increased in patients with diabetes, including C-reactive protein,^{20a} fibrinogen,^{19,21} and soluble cell adhesion molecules.^{22,23} Hyperglycemia increases the concentration of advanced glycation end-products (AGEs), which may be responsible in part for inflammation in the vascular wall.²⁴ Additional cellular mechanisms that have been proposed to contribute to the vascular abnormalities in patients with diabetes include increased flux through the polyol pathway and diacylglycerol-mediated protein kinase C (PKC) activation.²⁵

Pathology

Coronary atherosclerosis primarily affects the epicardial or large surface arteries of the heart. Coronary plaques in patients with diabetes have more lipid and macrophages than in control subjects.²⁶ CAD is generally more widespread in diabetes, with stenoses in a greater number of vessels and more obstructive lesions within each vessel.²⁷ In addition, diffuse disease involving long segments and/or the distal aspects of the artery may be present (Fig. 49-1). This is a critical finding, since distal disease adversely affects the suitability of the vessels for either percutaneous or surgical revascularization. In many cases, patients with diffusely diseased vessels can only be treated medically. Patients with diabetes also tend to have less collateral blood vessel development to areas supplied by arteries with severe stenoses.²⁸ This may reflect diminished angiogenesis in the diabetic myocardium. Obstruction of the left main coronary artery is more common in diabetic patients and often requires surgical revascularization.

Small vessel or microvascular disease has also been observed in myocardium from diabetic patients, including perivascular fibrosis, thickening of myocardial capillary basement membranes, and microaneurysms.^{29,30} The significance of these abnormalities is uncertain, particularly with regard to whether they limit coronary blood flow. In addition, functional abnormalities in the coronary endothelium are frequently seen in patients with diabetes (see below).³¹ Endothelial dysfunction may have an important role in limiting the augmentation of coronary blood flow during stress.

Prevention

The prevention of CVD in patients with diabetes is of paramount importance and requires a multifaceted approach to risk reduction (Table 49-1).³²⁻³⁹ Lifestyle recommendations should include intensive dietary management, weight control, regular physical activity, moderation in alcohol and sodium consumption, and smoking cessation when indicated. Hypertension (see Chap. 48) and dyslipidemia (see Chap. 47) should be aggressively treated. All patients with diabetes should strive to maintain optimal glycemic control and should be taking daily aspirin.

Exercise is an integral part of the management of both T1DM and T2DM, having beneficial effects on glycemic control, lipids, weight and blood pressure (see Chap. 23). However, individualized exercise recommendations are required in patients with peripheral or cardiovascular autonomic neuropathy, severe retinopathy, or

FIGURE 49-1. Diffuse coronary atherosclerosis. Coronary angiogram showing diffuse atherosclerotic narrowing (arrows) of the lumen of the mid and distal portions of the left anterior descending (LAD) and distal left circumflex (LCX) arteries of a 62-year-old patient with T2DM. Note the relatively normal caliber of the proximal portion of the LCX as compared to the diffuse narrowing of the LAD.

known CAD. Because of the possibility of unrecognized CAD, particularly in individuals with T2DM, these patients should generally engage in moderate-intensity exercise regimens. Sedentary individuals should always initiate exercise programs at a low level and gradually increase the intensity of exercise. All patients should be educated about the symptoms of myocardial ischemia and instructed to report them to their physician if they occur. When patients want to engage in high-intensity exercise, those with a long duration of diabetes, multiple CAD risk factors, or known diabetic complications should undergo screening for underlying CAD.³⁷

The benefit of hormone replacement therapy in the primary prevention of CVD in postmenopausal diabetic women remains controversial. Although the Heart and Estrogen/Progestin Replacement Study trial raised concern that hormone replacement might increase CVD events in women with known CAD,⁴⁰ hormone replacement as primary preventive therapy does not appear to have adverse cardiovascular effects. Case control studies suggest that the incidence of cardiac events may be lower in women who take hormone replacement.⁴¹ The current American Heart Association

TABLE 49-1. Primary Prevention of Cardiovascular Disease in Diabetic Patients

Goal	Strategies
<i>Blood pressure</i> <130/80	Measured at each visit Lifestyle modification Medication
<i>Lipids</i> LDL <100 mg/dL HDL >45 mg/dL in men; >55 mg/dL in women Triglycerides <150 mg/dL	Tested annually or every 2 years if low-risk Medical nutrition therapy Daily fat intake: <7–10% saturated fat and <200–300 mg cholesterol Regular physical activity Weight control Glycemic control Medication
<i>HbA_{1c}</i> <7%	Tested 2–3 times annually if meeting goal; 4 times annually if above goal or therapy changed Medical nutrition therapy Weight control Regular physical activity Self-monitoring of blood glucose Education in self-management and problem solving
<i>Physical activity</i> Regularly 3–4 times per week for 30 minutes	Routinely assess physical activity and exercise status Moderate aerobic regimen Increase in daily activities With multiple CAD risk factors, complications or long duration of diabetes, consider screening for CAD Individualization of prescription Caution with peripheral neuropathy or cardiac autonomic neuropathy or proliferative retinopathy
<i>Weight</i> BMI 21–25 kg/m ² Waist circumference <102 cm in men and <88 cm in women	Height, weight, BMI, and waist circumference at each visit Weight control Regular physical activity
<i>Smoking</i> Complete cessation	Assess smoking status Counseling on prevention and cessation Provide counseling, problem-solving or coping skills training, and pharmacotherapy
<i>Aspirin therapy</i> Consider	Consider enteric-coated aspirin 75–325 mg/d if age ≥40 years and 1 or more additional CAD risk factors
<i>Estrogen replacement</i> Consider	Consider in post-menopausal women with multiple CAD risk factors

BMI, body mass index; CAD, coronary artery disease; HDL, high-density lipoproteins; LDL, low-density lipoproteins.

(AHA) guidelines support the use of estrogen in postmenopausal women,³² particularly in women with multiple cardiac risk factors. Diabetic women should be taking daily aspirin before initiating hormonal therapy.

Although glucose control is more strongly linked with microvascular complications of diabetes than with macrovascular disease, optimal glucose control is important to the control of lipid levels, and may have an impact on cardiac events (see below).^{4,42,43} Both the American Diabetes Association (ADA) and AHA support the intensive treatment of diabetes with patient self-monitoring of blood glucose levels and target HbA_{1c} concentrations <7%.³²

Asymptomatic Ischemia

Diabetic patients sometimes have unrecognized CAD, causing asymptomatic episodes of myocardial ischemia. Asymptomatic or “silent” ischemia most often occurs in patients who also have

symptomatic ischemia with angina, but some patients with diabetes only experience asymptomatic episodes. Ischemia tends to occur more commonly without symptoms in diabetics than in nondiabetics during treadmill testing,⁴⁴ ambulatory electrocardiographic monitoring,⁴⁵ and coronary angioplasty balloon inflation.⁴⁶

The significance of asymptomatic ischemia depends on the extent of compromised myocardium, with some diabetic patients having only minor regions of ischemia and others having major ischemia. Of particular concern is asymptomatic ischemia which has caused prior MI, decreased left ventricular function, heart failure or ventricular arrhythmias. These patients are at high risk for subsequent cardiac events and therefore require complete evaluation usually including coronary angiography.

The mechanisms responsible for asymptomatic CAD in diabetic patients may include cardiac autonomic neuropathy (see Chap. 44).⁴⁷ The afferent sympathetic nerves contain fibers responsible for pain awareness during myocardial ischemia. Although the

is an appealing explanation for silent ischemia, diabetic patients with painful ischemia also have alterations in cardiac sympathetic innervation.⁴⁸ These latter findings suggest that additional factors likely inhibit the diabetic patient's awareness of ischemia.

Diagnosis

Routine electrocardiography sometimes reveals significant Q waves, deep T-wave inversions, or left bundle branch block (LBBB) in asymptomatic patients with diabetes. These findings should raise the possibility of a prior MI. In the Framingham study, 12% of diabetic patients had electrocardiographic evidence of prior MI and no symptoms of CAD.⁴⁹ The current ADA recommendations include a yearly electrocardiogram to evaluate older patients for the presence of CAD.³⁷

Asymptomatic CAD can also be detected through cardiac testing. Treadmill exercise electrocardiography is perhaps the least expensive and most widely used approach. ST-segment depression occurs in 12–54% of asymptomatic patients.^{45,50–52} Abnormal treadmill tests have been associated with retinopathy, male gender, and insulin treatment.⁵² However, standard exercise electrocardiography has limitations, including a relatively low sensitivity and a significant incidence of false positive tests (especially in patients with hypertension). In addition, a number of older diabetic patients are unable to exercise adequately, decreasing the utility of the test.

Cardiac assessment with either myocardial perfusion imaging or echocardiography has a greater sensitivity and specificity than exercise testing with electrocardiographic monitoring alone. These techniques can also be used along with pharmacologic stress (adenosine or dobutamine infusions) in patients who are unable to exercise well. The prevalence of asymptomatic myocardial ischemia detected by perfusion imaging ranges from 6–29% in patients with diabetes.^{53–55} Predictors of abnormal perfusion studies include increasing age, higher cholesterol level, male gender, proteinuria, and ST-T wave abnormalities on resting electrocardiogram.⁵⁵

Myocardial perfusion imaging not only improves the detection of CAD, but is also a well-recognized predictor of adverse cardiac outcomes in the overall population with either known or suspected CAD.⁵⁶ In one study of high-risk patients with T2DM (most of whom were asymptomatic), abnormal thallium perfusion imaging was associated with a 2.9-fold greater risk of nonfatal MI and a 5.7-fold greater likelihood of a major event (MI or death).⁵⁷ A greater number of abnormal segments on perfusion imaging pre-

dicted a higher incidence of subsequent events. Large, reversible myocardial perfusion defects are sometimes found in asymptomatic diabetic patients and indicate significant areas of potentially jeopardized myocardium (Fig. 49-2).

Screening

The strategy of screening the overall population of patients with diabetes for asymptomatic CAD remains highly controversial. The rationale for screening is that early detection of CAD will lead to interventions that will lower the risk of irreversible cardiac events (MI and death). An effective screening program incorporates tests that not only accurately identify the presence of CAD, but more importantly have predictive value for future cardiac events. Clinical investigations, such as the Detection of Ischemia in Asymptomatic Diabetics (DIAD) study, are under way to address the efficacy of screening for CAD in patients with diabetes.

The identification of asymptomatic CAD has clear implications for the care of the diabetic patient. It strongly reinforces the need to reduce modifiable cardiovascular risk factors, which often requires multiple medications to optimally treat dyslipidemia and hypertension. In some patients it may lead to the initiation of lipid-lowering therapy. Although the ADA recommends that LDL cholesterol levels be less than 100 mg/dL, the current guidelines do not necessarily call for the initiation of pharmacologic therapy for levels between 100 and 130 mg/dL unless macrovascular disease is present.³⁴ A heightened concern for CAD can motivate efforts at smoking cessation and weight reduction, which otherwise may be difficult to accomplish. Once CAD is identified, physicians are more apt to assure the patient's compliance with daily aspirin treatment and to consider the use of beta-blockers to prevent ischemia. Recommendations for regular exercise are reinforced with limitations placed on very strenuous activity which might place the patient at risk for a cardiac event.

Abnormal noninvasive cardiac testing in patients with diabetes sometimes results in coronary angiography. When critically blocked coronary vessels are detected, patients often undergo coronary revascularization with the rationale that the cardiac event rate will be reduced by such intervention. However, there are risks associated with either percutaneous revascularization or coronary artery bypass grafting which need to be carefully considered (see below). The efficacy of these procedures in improving outcomes in asymptomatic diabetic patients is unproven, although revascular-

FIGURE 49-2. Asymptomatic ischemia. Myocardial perfusion images demonstrating a large defect in the anterolateral region (arrows) of the left ventricle on the exercise stress images (top row), which has largely resolved in the rest images (bottom row). This anterolateral ischemia was due to a 90% stenosis in the middle portion of the left anterior descending artery in an asymptomatic 54-year-old man with T2DM, hypertension, mild obesity, and low HDL cholesterol.

ization does improve outcomes in diabetic patients with mild angina and abnormal cardiac testing.^{58,59} The Bypass Angioplasty Revascularization Intervention (BARI) II trial, which is now under way to compare the utility of contemporary medical therapy with or without revascularization in diabetic patients, will help to clarify this important issue. At the current time, revascularization is generally reserved for high-risk patients.

The ADA has published guidelines for CAD screening and risk stratification in high-risk individuals with diabetes.³⁷ Exercise stress testing with myocardial perfusion imaging or echocardiography is recommended for risk stratification in the patient with cardiac symptoms or evidence of ischemia or MI on electrocardiogram. In the asymptomatic patient with diabetes, screening is considered in patients with peripheral or carotid occlusive disease, cardiovascular autonomic neuropathy, or multiple (2 or more, including microalbuminuria) cardiac risk factors in addition to diabetes.

Medical Treatment

Once the diagnosis of CAD is made in patients with diabetes, an intensive effort is required to modify coronary risk factors, following many of the same principles outlined for the primary prevention of CAD (Table 49-1). A multifaceted approach should include aggressive treatment of dyslipidemia and hypertension, prevention of thrombosis with aspirin, and medications to reduce the occurrence of myocardial ischemia. The goals of this intensive therapy are to decrease the likelihood of subsequent cardiac events and death, to slow the progression of coronary atherosclerosis, and to prevent ischemic symptoms.

Anti-Ischemic Medication

Specific therapy for angina in diabetic patients should include beta-blockers, which prevent ischemia and improve exercise tolerance. Chronic beta-blocker therapy in diabetic patients with CAD reduces the cardiac event rate.⁶⁰ The overall benefit of these medications outweighs their potential for worsening glycemic control in patients with T2DM and for masking hypoglycemia in patients requiring insulin. However, they should be used with caution and should be avoided if possible in the presence of bronchospastic lung disease, active heart failure, and significant sinus or atrioventricular node disease.

Angiotensin-converting enzyme (ACE) inhibitors have an important role in the treatment of CAD in diabetic patients, particularly in the presence of heart failure, decreased left ventricular function, or hypertension (see below). However, they may also have a more generalized benefit in preventing cardiac events in diabetic patients with CAD. In the recent Heart Outcomes Prevention Evaluation (HOPE) study, ACE inhibitors decreased cardiac events in a broad group of patients which included diabetics with and without CAD.⁶¹ This benefit may derive from the stabilization of coronary plaques and prevention of unstable coronary syndromes.

Nitrates are useful for the symptomatic relief and prevention of angina, but need to be used with caution in patients with autonomic neuropathy. Calcium channel blockers are also helpful in the treatment of angina and have an important role in controlling blood pressure in hypertensive type 2 diabetics.

Lipids

Treatment of lipid abnormalities is critically important in diabetic patients with CAD. The beneficial effect of lipid lowering is both to stabilize existing plaque and prevent acute coronary

syndromes, and to slow the progression of atherosclerosis. Although diabetes does not increase LDL cholesterol, most diabetic patients with CAD benefit from treatment with an HMG-CoA reductase inhibitor (statin). In the Scandinavian Simvastatin Survival Study (4S), treatment with simvastatin decreased the coronary event rate by 40% over 5 years of follow-up in diabetic patients with high LDL cholesterol and known CAD.⁶² In the Cholesterol and Recurrent Events (CARE) study, there was a 25% reduction in cardiac event rate in diabetic patients with average LDL cholesterol levels who were treated with pravastatin.⁶³ Interestingly, in the Atorvastatin versus Revascularization Treatment (AVERT) study, high-dose atorvastatin treatment was as effective as angioplasty in reducing cardiac events and ischemia in mildly symptomatic patients with low-risk stress tests.⁶⁴ Although this study included patients with diabetes, whether they had the same benefit as nondiabetic patients was not assessed. In addition, the angioplasty-treated patients did not receive as aggressive lipid-lowering treatment, so it remains uncertain as to whether angioplasty has an additional beneficial effect when combined with intensive lipid-lowering treatment. This issue is currently being evaluated in the ongoing Clinical Outcome Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial.

Many patients with T2DM have pronounced abnormalities in HDL cholesterol and triglycerides with relatively normal concentrations of LDL cholesterol. In these patients, treatment with fibrates may be beneficial in preventing cardiac events. The Helsinki Heart Study suggested that gemfibrozil treatment reduced the incidence of CAD in patients with T2DM.⁶⁵ In the Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA HIT) study, gemfibrozil decreased cardiac events by 20% in patients with CAD who had low HDL (<40 mg/dL) and average LDL cholesterol (<140 mg/dL) levels.⁶⁶ Some diabetic patients have high LDL cholesterol and low HDL/high triglycerides, which remain abnormal after treatment with a statin. In this case, the combined use of a statin and fibrate may be helpful in normalizing the lipid profile. However, there are no outcome data yet showing that this combination of drugs is better than either alone, and there is some potential for the development of myositis with combined therapy.

Antithrombotic Agents

Aspirin inhibits platelet thromboxane synthesis and aggregation, preventing coronary thrombus formation in patients with diabetes. Despite the increased platelet reactivity that occurs in diabetic patients, cardiac events are reduced by relatively low doses of aspirin. In the Physicians Health Study, 325 mg of aspirin every other day reduced the incidence of MI by 60% in diabetic physicians.⁶⁷ In the Early Treatment Diabetic Retinopathy Study (ETDRS), 650 mg of aspirin per day reduced the cardiac event rates in diabetic patients.⁶⁸ In the Hypertension Optimal Treatment (HOT) trial, 75 mg of aspirin reduced cardiovascular events by 15% and the incidence of MI by 36% in patients with diabetes.⁶⁹ Thus it would appear that low-dose aspirin (75–325 mg per day) is effective in reducing cardiac events in diabetic patients with CAD.

A second mechanism involved in thrombosis is ADP-mediated activation of platelets. Agents such as ticlopidine and clopidogrel block this pathway and are effective in inhibiting platelet aggregation. In the Clopidogrel versus Aspirin in Patients at Risk for Ischemic Events (CAPRIE) study, clopidogrel was slightly more effective than 325 mg of daily aspirin in preventing cardiovascular events.⁷⁰ Although diabetic patients were included in this study, the analysis did not specifically assess the efficacy of clopidogrel in

this subgroup. In addition, these agents are more expensive than aspirin and may rarely cause granulocytopenia and thrombotic thrombocytopenic purpura. These agents are used routinely following coronary stent placement (see below) and in chronic CAD in patients allergic to or unable to take aspirin.

Revascularization

Careful consideration is warranted when deciding whether and by what means a patient with diabetes should undergo coronary artery revascularization. The number, location, morphology, and extent of coronary stenoses are the primary features determining the appropriateness of percutaneous intervention or coronary artery bypass grafting (CABG). The presence of left main stenosis, multivessel disease, or long complex proximal lesions favors the use of CABG. This assumes that the distal vessels are suitable targets with good run-off, and that the patient does not have excessive comorbidity. In the case of a single discrete proximal stenosis, current trends favor the use of percutaneous intervention when technically feasible. In a small number of patients with diabetes, coronary angiography reveals multivessel disease, which is technically suitable for either percutaneous intervention or CABG. Management of these patients remains controversial as discussed below.

Coronary Artery Bypass Grafting

CABG has an important role in the management of CAD patients with diabetes, who generally derive excellent symptomatic improvement from this procedure. In the current era, patients with diabetes have a 95–99% chance of surviving the initial surgery.^{71–73} In-hospital mortality is higher in older patients and when surgery is performed on a nonelective basis following presentation with unstable angina or MI.⁷⁴ Gender also has an impact on the risk of CABG in patients with diabetes,^{74,75} with women having a twofold higher operative mortality than men.⁷²

Operative Complications

Diabetic patients are at somewhat increased risk for both cardiac and noncardiac complications associated with CABG. The most serious complications are postoperative MI, stroke, renal failure, and sternal wound infection.^{73,76} The development of a new Q-wave MI is a serious complication of CABG that occurs slightly more often in patients with diabetes compared to those without diabetes.^{73,77} In the BARI trial, new Q-wave MI was found in 5.8% of the patients with diabetes versus 4.3% of those without diabetes. Potential causes of MI are ischemia prior to cardiopulmonary bypass, an inability to graft diseased vessels, and air or atherosclerotic coronary embolization.

Patients with diabetes are also at increased risk for stroke during CABG. The incidence of stroke is twice as high in diabetics as in nondiabetics and ranges from 2–4% in patients with diabetes.⁷³ Older patients with diabetes with a history of prior stroke, as well as those with calcification of the ascending aorta or renal failure,⁷⁸ are at particular high risk, and these indications sometimes mitigate against proceeding with surgery.

Postoperative renal failure occurs more commonly in patients with diabetes.⁷⁹ Those with preoperative renal insufficiency are at particular risk and the use of ACE inhibitors immediately post-CABG may precipitate oliguria in these patients.⁸⁰ Preoperative renal insufficiency is also a marker of general risk during CABG, since it often occurs in older patients with diabetes and those with peripheral vascular disease, hypertension, or left ventricular

dysfunction.^{81,82} Diabetic patients on dialysis are at particularly high risk, with operative mortalities as high as 10–15%.⁸³ These patients often require more prolonged mechanical ventilation, and more frequently develop atrial fibrillation and gastrointestinal complications following CABG.

Sternal wound infections occur in 8–10% of diabetic patients undergoing CABG, which is three- to fivefold more often than in nondiabetic subjects.^{71,84} The majority of these are successfully treated with antibiotics, but occasionally operative debridement is necessary. The risk of sternal wound infection may be increased when preoperative blood glucose levels are >200 mg/dL.^{85,86} Although there is some concern that the use of one or both internal mammary artery (IMA) grafts may devascularize the sternum and predispose to sternal complications in diabetic patients, recent investigations have not found a relationship between the type of graft and infection.^{71,87} Antibiotic prophylaxis is given within the 2 hours preceding surgery to minimize the risk of infection.⁸⁸

Long-Term Outcomes

Although most diabetic patients derive significant symptomatic benefit from CABG, they do have somewhat less favorable long-term outcomes than those without diabetes. Compared to nondiabetic subjects, the overall survival of diabetic patients after CABG is reduced from approximately 90% to 80% at 5 years, and from 80% to 65% at 7–10 years.^{73,75} This reflects in part their more advanced cardiac disease and comorbidity at the time of surgery. Predictors of worse long-term outcomes following CABG include preoperative stroke, hypertension, heart failure, high glucose levels, proteinuria, multivessel disease, male sex, left ventricular dysfunction, and surgery with less than three grafts.^{73,75,89}

A higher incidence of angina and heart failure also occurs following CABG in patients with diabetes.⁷⁵ This relates to less complete revascularization due to the presence of diffuse disease, more rapid progression of native disease, increased risk for saphenous vein occlusion, and a tendency to have or develop heart failure (see below). However, the BARI trial reported that over a 7-year period, repeat CABG was performed in only 2% of patients and PTCA in 9% of patients.⁹⁰

The use of an IMA graft during CABG is important in the overall population, but appears to be critical in patients with diabetes.^{71,75,77} The long-term patency of the left IMA is superior to that of saphenous vein grafts. In the BARI trial, the 5-year cardiac mortality after CABG was less than 2% in those who received an IMA graft.⁷⁷ The 7-year total mortality was 17% when an IMA graft was used, but 45% when only saphenous veins were utilized.⁹⁰ This may relate in part to the protection afforded by grafting the left IMA to the left anterior descending artery, which supplies the important anterior wall of the left ventricle. Following revascularization with either CABG or PTCA for multivessel disease, patients with diabetes have an 8% risk of developing a Q-wave MI over the next 5 years. In these patients survival at the time of MI is considerably better if they have had prior CABG.⁹¹

Percutaneous Transluminal Coronary Angioplasty

Percutaneous coronary intervention most commonly involves PTCA or intracoronary stent placement in patients with diabetes. Coronary atherectomy and laser and rotablator interventions are much less commonly utilized. Percutaneous intervention has an important role in the treatment of single-vessel CAD in diabetic patients. It results in excellent symptomatic improvement in diabetic

patients with angina. Percutaneous interventions are also attractive in that they avoid the initial complications of CABG in patients at high risk for surgery because of significant comorbidity.

Complications

The primary initial risk of PTCA is coronary occlusion leading to MI. Although the early use of PTCA was associated with increased rates of nonfatal MI and death in diabetic patients,⁹² the current results have improved and are comparable to those in nondiabetics. PTCA is now successful in over 99% of diabetic patients, with an overall mortality of 0.4–1%.^{77,93,94} The risk of MI (evidenced by an increase in cardiac enzymes) is 3–5%, but significant or Q-wave MI occurs only in 0.5–2% of diabetic patients. The risks are higher in multivessel angioplasty. The use of intensive antiplatelet treatment, including the glycoprotein IIb/IIIa antibody fragment abciximab, has substantially lowered the risk of thrombosis formation, MI, and death during PTCA in diabetics.⁹⁴ When PTCA fails, urgent CABG is required in 0.5% of diabetic patients.

In addition to the cardiac risks, percutaneous coronary interventions may cause vascular complications or renal failure, particularly in older diabetic patients with underlying diffuse vascular disease and renal insufficiency. Stroke due to embolization of atheromatous material or thrombus from the aorta is the most serious vascular complication, and occurs in 0.2–0.6% of diabetic patients undergoing PTCA.^{77,94} Atheroembolic showering to the kidneys, mesenteric circulation, and periphery rarely occur. Femoral artery catheterization may be complicated by retroperitoneal bleeding, femoral hematoma, femoral or iliac artery occlusion, or pseudoaneurysm formation. Patients with diabetes are also at increased risk for contrast nephropathy, which may be prevented in part by forced diuresis⁹⁵ and the administration of the antioxidant acetylcysteine.⁹⁶

Long-Term Outcomes

The long-term outcomes of PTCA in diabetes are less favorable than in nondiabetic patients (Table 49-2).^{92,93,97} Following PTCA, mortality was twofold higher in diabetic than in nondiabetic patients over follow-up periods ranging from 2–9 years, with differences evident as soon as 1.5 years after PTCA.⁹³ Diabetic patients experience more MIs following PTCA than nondiabetic patients. They also have a greater need for CABG and repeat PTCA due to recurrent ischemia.⁹³ Patients with diabetes, as well as older patients and those with decreased left ventricular function, heart failure, multivessel disease, and proteinuria have decreased survival after PTCA.^{92,93,97,98}

A major determinant of the adverse long-term outcomes of PTCA in patients with diabetes has been the high rate of restenosis. Restenosis occurs in 25–40% of diabetics within the first months after PTCA and often leads to the recurrence of symptoms.^{99–101} In small or diffusely diseased vessels, and in saphenous vein grafts the restenosis rate is in excess of 50%. Restenosis is often symptomatic, requiring repeat PTCA or CABG, but when unrecognized may contribute to long-term mortality in patients with diabetes following angioplasty.

The increased incidence of restenosis following PTCA in diabetics is attributed in part to the smaller intraluminal diameter achieved during the balloon dilatation, and in part to the accelerated neointimal hyperplasia which occurs in these patients.¹⁰ The latter reflects greater impairment in endothelial function, increased smooth muscle cell proliferation. Increased thrombus formation at the site of balloon dilatation may trigger the smooth muscle cell response, which may then be enhanced by hyperlipidemia and insulin-like growth factor-1.

Intracoronary Stents

The use of intracoronary stents has improved the outcomes of percutaneous coronary revascularization. With recent progress in the development of stents and device delivery technology, stents are now used in the majority of interventional procedures.¹⁰ Coronary stents achieve a greater luminal diameter than PTCA. They also prevent the coronary artery dissection that sometimes complicates PTCA and can lead to complete vessel occlusion. The development of smaller stents has also permitted more widespread use in patients with diabetes.

The outcomes of intracoronary stents in patients with diabetes have been evaluated in a number of studies over the last 5 years (Table 49-3).^{99–101,106,107} Initial reports suggested a 1.5–2 times higher rate of early thrombosis and later restenosis following stent placement in diabetic patients. Increased restenosis in patients with diabetes reflects greater neointimal proliferation through the stent and results in a more frequent need for repeat revascularization. Restenosis is a particular problem in patients treated with insulin who also have a lower cardiac event-free survival.¹⁰⁰

Recent studies have demonstrated that diabetic patients benefit from vigorous initial antiplatelet therapy after stent placement. Standard therapy during stent placement includes aspirin, clopidogrel and heparin, followed by aspirin and clopidogrel for weeks, and then indefinite aspirin therapy. With the additional use of abciximab prior to device delivery and for 12 hours afterward, the risks of stent thrombosis and resulting MI have decreased.

considerably. In addition, intensive early platelet inhibition may also prevent platelet vessel wall interaction, which is important in initiating the restenosis process. The multicenter Evaluation of Platelet IIb/IIIa Inhibitor for Stenting (EPISTENT) trial also demonstrated that infusion of abciximab reduced by half the need for repeat coronary revascularization during the 6 months following stent placement in diabetic patients (Table 49-4).^{94,108} In addition, combined rates of death and MI were also reduced in diabetic patients at 6 months.

The use of stents in diabetic patients is a rapidly evolving field. Although the intermediate-term results are encouraging, long-term outcomes and the use of stents in patients with multivessel CAD remains to be determined. The effect of other glycoprotein IIb/IIIa inhibitors (tirofiban, eptifibatide) on stent outcomes in diabetes needs

to be further evaluated. Finally, biologically-coated stents and brachytherapy (local radiation to prevent neointimal proliferation) are emerging as important approaches to preventing restenosis in diabetic patients.

Multivessel Disease

Patients with diabetes are often found to have multivessel CAD. The majority of these patients are clearly best revascularized by CABG, but a subgroup have localized stenoses that are potentially amenable to either CABG or multivessel percutaneous intervention.

These different strategies have been compared in both randomized clinical trials and observational studies (Table 49-5).^{77,91,109–112} A major concern about the use of multivessel

CABG, coronary artery bypass grafting; PTCA, percutaneous transluminal coronary angioplasty; RCT, randomized clinical trial.

PTCA was raised by the BARI trial, which randomized patients to either PTCA or CABG in the late 1980s.⁷⁷ In the subgroup of patients with diabetes (on treatment), both the cardiac and overall mortality were higher in those undergoing PTCA than in those treated with CABG after 5 years.^{77,113} In contrast, there was no survival difference observed in the nondiabetic patients. In diabetic patients receiving an IMA graft during CABG, the cardiac mortality at 5 years was only 3%, while in those in whom only saphenous vein grafts were used the mortality was 18%, which was similar to that seen with PTCA (21%). The survival advantage associated with CABG in diabetic patients occurred despite a higher risk of Q-wave MI (6% versus 1.4%) and in-hospital mortality (1.2% versus 0.6%) at the time of the initial procedure. Other randomized clinical trials have included patients with diabetes and overall have also shown a survival benefit from CABG.^{109,114,115}

The adverse outcomes of PTCA in multivessel CAD in diabetes led to an alert, cautioning about the use of multivessel angioplasty in patients with diabetes,¹¹⁶ and to the suggestion that multivessel PTCA be abandoned in diabetic patients.¹¹⁷ However, in nonrandomized studies, the survival with multivessel PTCA and CABG has been equivalent.^{110,112} This may be explained in part by the tendency of patients treated with CABG to be at higher risk than those treated with angioplasty in nonrandomized studies. In addition, completeness of revascularization is better in subjects undergoing CABG (79–81%) as compared to those undergoing angioplasty (16–42%).^{111,112} Although CABG is often the preferred means of revascularization in diabetics, percutaneous revascularization may be warranted in the future with the use of coronary stents, more effective platelet inhibitors, intensive risk factor management, and careful observation following the initial procedure.

Acute Myocardial Infarction

Acute MI is a common event in patients with diabetes. The incidence of MI in patients with T2DM was approximately 15 per 1000 patient-years in the UKPDS, while the incidence of fatal MI was 7 per 1000 patient-years.² MI may occur without the warning of prior angina, and patients may have atypical symptoms which delay their seeking medical attention. In some cases, these patients succumb to ischemic arrhythmias and never reach the hospital.^{118,119} In addition, studies have consistently documented a twofold higher mortality and increased morbidity associated with acute MI in patients with diabetes. The poor natural history of MI in diabetic patients is highlighted by studies during the 1960s from the Joslin Clinic, in which early mortality approached 40%.¹²⁰ Although early coronary reperfusion, aspirin, beta-blockers, ACE inhibitors, lipid-lowering agents, and coronary revascularization have dramatically improved the survival of diabetic patients with MI, these patients still have a higher risk of complications than nondiabetic patients.

Complications Associated with Acute MI

Patients with diabetes have an increased incidence of complications associated with acute MI. Most problematic of these are heart failure, cardiogenic shock, and postinfarct angina.^{121,122} These problems result in part from the more extensive multivessel and left main coronary artery disease found in diabetic patients. Heart block, atrial arrhythmias, and renal insufficiency have also been reported more frequently during the post-MI period in patients with diabetes.^{123,124} Recurrent MI is also somewhat more common in individuals with diabetes.^{124–127}

Heart failure is a particular problem in diabetic patients during and following acute MI.^{125,128} Heart failure develops more

commonly, even though the index infarctions are no larger than those in nondiabetic patients.¹²⁹ Heart failure may result from more extensive CAD causing ischemia in regions outside the infarct area, or from prior scarring in remote regions. Diabetes-related diastolic dysfunction and impaired systolic reserve (discussed below) may compromise the ability of the heart to cope with the stress of acute infarction. In addition, coexistent hypertension and renal disease may further promote the development of symptomatic heart failure.

Treatment of Acute MI

Overall, patients with diabetes are at high risk during MI and benefit from aggressive therapy, including early reperfusion for ST-segment elevation MI.

Thrombolytic Therapy

Patients with ST-segment elevation MI, in whom there is typically acute thrombotic occlusion of a coronary artery, require prompt treatment to reestablish myocardial reperfusion. In centers without cardiac catheterization facilities, this is achieved with thrombolytic therapy. Support for this approach comes from subgroup analyses of diabetic patients in the large thrombolytic trials carried out in the 1980s and 1990s, including the Thrombolysis and Angioplasty in Myocardial Infarction (TAMI) study,¹³⁰ the International Tissue Plasminogen Activator/Streptokinase (TPA/SK) trial,¹³¹ the Second International Study of Infarct Survival (ISIS-2),¹³² and the Gruppo Italiano per lo Studio Della Sopravvivenza nell'Infarto Miocardico (GISSI)-2 study.¹³³ Although thrombolytic therapy improved survival, both in-hospital and late mortality was 1.5- to 2-fold higher in diabetic than in nondiabetic patients. In the patients treated with insulin, and in diabetic women,^{125,131} a higher in-hospital and 6-month mortality persists, highlighting the need for improved therapies in these high-risk patients.

Several factors may lead to less-than-optimal responses to thrombolysis in patients with diabetes, including more extensive CAD, diffuse disease with poor run-off in the occluded vessel, and their increased tendency toward thrombosis at the site of plaque rupture. Increased plasminogen activator inhibitor (PAI-1) levels, platelet hyperreactivity, increased concentrations of hemostatic proteins, and endothelial dysfunction promote thrombosis in diabetes. Thus improved strategies of thrombolysis and subsequent antithrombotic treatment to prevent reocclusion are needed in patients with diabetes.

Percutaneous Coronary Reperfusion

In many centers, primary angioplasty or intracoronary stent placement is the preferred treatment for acute MI, in that it provides more effective reperfusion, and definitive information on the extent of CAD, and avoids the use of thrombolytic agents. While the major primary angioplasty and stent trials have included patients with diabetes, in many the outcomes of patients with diabetes have not been specifically evaluated.^{134,135} The Global Use of Strategies to Open Occluded Arteries in Acute Coronary Syndromes (GUSTO-IIb) Angioplasty Substudy did report the outcomes of the subgroup of 177 diabetic patients, randomized to thrombolysis (alteplase) or PTCA (8.6% with stent placement) between 1994 and 1996.¹³⁶ In the overall cohort of both diabetic and nondiabetic patients, primary PTCA led to better outcomes at 30 days with respect to the primary composite end point of death, reinfarction, and disabling stroke. The diabetic substudy was underpowered, but showed a similar trend in the diabetic patients and a significant reduction in recurrent ischemia and reinfarction with PTCA.¹³⁶

The long-term outcomes after MI treated with primary PTCA are adversely influenced by the presence of multivessel disease, left ventricular dysfunction, and the development of restenosis, all of which are more common in patients with diabetes. In GUSTO-IIb, the 1-year mortality was similar in the diabetic patients treated with thrombolysis or primary PTCA,¹³⁶ which may reflect the high incidence of restenosis after PTCA in diabetic patients (see below). At present, myocardial placement of intracoronary stents with adjuvant antithrombotic treatment with glycoprotein IIb/IIIa inhibitors is a common approach to treating ST-segment elevation MI in patients with diabetes. This approach is intended to provide more complete and secure early reperfusion and may diminish the rate of restenosis (see below).

Thus diabetic patients with ST-segment elevation who are within 12 hours of the onset of symptoms should be considered for primary angioplasty with stent placement, particularly when there is evidence of heart failure or hemodynamic stability, where the establishment of secure vessel patency may be critical. Multi-vessel disease is identified more commonly in diabetic than non-diabetic patients at the time of primary angioplasty. While angioplasty or stent placement in the "culprit" lesion is preferable for treatment of the acute MI in most cases, a small number (~5%) of diabetic patients require urgent surgical revascularization.¹³⁶ When PTCA or stent placement in the "culprit" lesion leaves significant residual CAD, the presence of recurrent angina or inducible ischemia indicates a need for subsequent revascularization.

Beta-Blockers

Beta-blockers decrease chest pain, limit the amount of myocardial damage, and improve prognosis in the setting of acute MI. In patients with diabetes included in large trials, beta-blockers reduced mortality by 36% during acute MI.^{137,138} Contraindications to the use of beta-blockers during MI include bradycardia, hypotension, atrioventricular nodal block, moderate or severe heart failure, or active wheezing. Beta-blockers should be given to patients regardless of administration of thrombolytic therapy or primary PTCA. They are especially useful to treat continuing or recurrent ischemic chest pain or rapid atrial fibrillation. Since diabetic patients often have significant heart failure during MI, patients treated with beta-blockers should be carefully monitored.

ACE Inhibitors

Treatment of patients with ACE inhibitors reduces afterload, prevents adverse myocardial remodeling, and decreases heart failure and mortality following MI. In the GISSI-3 study, in the subgroup of patients with diabetes treated with lisinopril for 6 weeks, the mortality was reduced from 12.4% to 8.7%, and this benefit persisted for 6 months after completion of therapy.¹³⁹ ACE inhibitors also appear to have long-term benefit in patients with diabetes following MI, as demonstrated by the subgroup analysis of the Survival and Ventricular Enlargement (SAVE) trial.¹⁴⁰

Insulin Treatment

The infusion of glucose-insulin-potassium (GIK) during acute MI lowers free fatty acid concentrations, improves myocardial metabolism, and may prevent apoptosis and necrosis.¹⁴¹ In addition to these early beneficial effects, intensive treatment of diabetes may stabilize the coronary vasculature and prevent recurrent events after acute MI. In the Diabetes Insulin Glucose in Acute MI (DIGAMI) trial, intravenous insulin infusion during the initial 24 hours, followed by intensive insulin treatment for 3 months,

reduced mortality at 1 year from 26% to 19%¹⁴² and at 3 years from 44% to 33%.¹⁴³ Interestingly, the largest impact was seen in those with a low-risk cardiovascular profile and no previous insulin treatment. The benefit of intensive treatment after discharge may be mediated by favorable effects on platelets, lipoproteins, tissue plasminogen activator-1 activity, vascular reactivity, or ventricular remodeling. However, because DIGAMI was a relatively small study, the current ACC/AHA guidelines caution that routine insulin use is not indicated until confirmatory results have been obtained.¹⁴⁴

There is some concern that intensive diabetes treatment may cause hypoglycemia and trigger myocardial ischemia in diabetic patients. Hypoglycemia does trigger catecholamine release and increase heart rate and blood pressure. However, these potential negative effects need to be considered within the overall context of the benefits of improved glucose control. Although there was an increased risk of hypoglycemia in intensively treated patients in the DIGAMI study, this risk was outweighed by the benefits of intensive treatment. In addition, diabetic patients presenting with acute MI often are hyperglycemic, and those with poor glucose control are at particularly increased risk.^{145,146} Thus improvement in glycemic control is generally considered an important goal in patients during and after acute MI, and further information is needed to determine the optimal means to achieve this goal.

Acute Coronary Syndromes

Unstable angina and non ST-segment MI are now considered part of a spectrum of acute coronary syndromes which have an increased risk for adverse outcomes.¹⁴⁷ These syndromes are characterized by progressive or prolonged anginal symptoms and often result from plaque rupture and intracoronary thrombus formation. The presence of diabetes is an independent risk factor for death, progression to acute ST-segment elevation, myocardial infarction, and subsequent readmission for unstable angina within the next year.¹⁴⁸

Diabetic patients with unstable angina have coronary vascular instability, as evidenced by a higher incidence of ulcerated plaques and intracoronary thrombi observed during coronary angiography.¹⁴⁹ They also have more extensive CAD, involving a greater number and longer segments of vessels and more often involving the left main coronary artery. Particularly difficult to manage are diabetic patients with acute coronary syndromes who have had prior CABG and present with imminent closure of a heavily diseased saphenous vein graft. In these patients, symptoms often persist despite medical therapy and revascularization strategies are less than ideal.

The management and outcomes of patients with acute coronary syndromes in diabetic patients are also complicated by their higher comorbidity. The presence of hypertension, peripheral and cerebral vascular disease, left ventricular hypertrophy (LVH), and heart failure increase their overall risk. Cardiovascular autonomic dysfunction also complicates the management of acute coronary syndromes in patients with diabetes. Autonomic neuropathy may result in an increased heart rate (due to predominant parasympathetic neuropathy) and a decreased awareness of ischemic symptoms.

Treatment

The initial therapy of acute coronary syndromes includes the administration of beta-blockers, aspirin, heparin, and nitrates.

Recent studies suggest that further platelet inhibition by the addition of a glycoprotein IIb/IIIa inhibitor to standard therapy, improves outcomes in patients with unstable angina. In the Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy (PURSUIT) trial, eptifibatide reduced the composite end points of death or nonfatal MI at 30 days.¹⁵⁰ In the Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms (PRISM-PLUS) study, tirofiban also reduced death or MI at 3 days.¹⁵¹ Although these trials included patients with diabetes, they were not designed to examine this specific subgroup. However, patients with diabetes have increased platelet reactivity and may derive significant benefit from the addition of these agents, particularly in the presence of significant ischemia or unremitting angina.

Many patients are initially stabilized with anti-ischemic and antithrombotic therapies, but some remain at significant risk for subsequent cardiac events. This has led to the widespread utilization of an invasive strategy with early coronary angiography and revascularization in the management of acute coronary syndromes. However, there has been recent debate as to whether an invasive strategy is preferable to a more conservative strategy with medical therapy and noninvasive testing to detect the subgroup of patients at high risk for subsequent events. In the Veterans Affairs Non-Q-Wave Infarction Strategies in Hospital (VANQWISH) trial, mortality or MI was not significantly different in those randomized to an invasive versus conservative strategy.¹⁵² In the Fragmin and Fast Revascularization During Instability in Coronary Artery Disease II trial (FRISC II), individuals with unstable angina treated with an invasive strategy had a 30–40% lower risk of death and MI as compared to those treated with a noninvasive strategy.¹⁵³ Neither study was powered to evaluate the outcomes specifically in diabetic patients.

In diabetic patients with acute coronary syndromes who respond to initial medical therapy, the decision whether to pursue angiography and revascularization needs to be individualized. The recent American College of Cardiology/American Heart Association (ACC/AHA) guidelines do not make generalized recommendations on the utilization of an initial invasive approach in diabetic patients.¹⁴⁷ An invasive strategy may be preferable in high-risk patients, including those with marked or widespread ST-segment depression, elevated troponin levels prior to MI, decreased left ventricular function, or heart failure. A noninvasive approach with further risk stratification based on stress echocardiography or myocardial perfusion imaging may be preferable in lower-risk patients and those with major comorbidity who are at high risk for the invasive approach.

HEART FAILURE

Epidemiology

Heart failure causes substantial morbidity in patients with diabetes, including both exertional limitation and recurrent hospitalization for shortness of breath. The Framingham Study demonstrated that the age-adjusted risk of developing heart failure was increased 2.4-fold in diabetic men, and 5.1-fold in diabetic women, with an overall incidence of heart failure of 22–27 per 1000 patient years.¹⁵⁴ Although the majority of these patients had T2DM, those treated with insulin had a four- to fivefold increased risk of heart failure compared to nondiabetic patients.

Etiology

The risk of heart failure in patients with diabetes persisted in the Framingham study after adjustment for age, hypertension, hypercholesterolemia, obesity, and clinically evident CAD.¹⁵⁴ However, there were few patients with heart failure who did not have CAD, hypertension, or rheumatic heart disease. Indeed, clinical heart failure is attributed in large part to coexistent CAD and/or hypertension, although abnormalities in left ventricular function related to diabetes may predispose the patient with these conditions to heart failure (see below).

CAD and Heart Failure

Atherosclerotic CAD is the most common cause of heart failure in the U.S. population¹⁵⁵ as well as in patients with diabetes.¹⁵⁴ Although the risk of developing heart failure in patients with diabetes persisted after accounting for clinically-evident CAD in the Framingham study, CAD was excluded only on the basis of absent clinical symptoms and electrocardiographic findings. In addition, the prevalence but not the extent of CAD was evaluated, and it is likely that the diabetic patients had more extensive CAD, which accounted in part for their increased incidence of heart failure. Additional recent cohort studies have also implicated diabetes as a risk factor for heart failure independent of CAD,^{156,157} but these studies again excluded CAD only on the basis of clinical history or discharge diagnosis. Unexplained heart failure in a patient with diabetes should prompt evaluation for CAD, often including cardiac catheterization.

Myocardial ischemia resulting from CAD may cause heart failure through impairment in systolic contractile function. In some cases, the diabetic patient presents with a typical dilated ischemic cardiomyopathy where the left ventricle contracts poorly, is enlarged, and has focal regional wall motion abnormalities (Fig. 49-3). Some of these patients have clinically documented or clear electrocardiographic evidence of a prior MI, which has led to fibrosis, progressive left ventricular enlargement, and heart failure.¹⁵⁸ In other cases, more diffuse CAD has caused diffuse patchy fibrosis, without a history or clear electrocardiographic evidence of MI, which nonetheless has caused progressive deterioration in ventricular systolic function.

FIGURE 49-3. Ischemic cardiomyopathy. Echocardiogram demonstrating the cross-sectional images of an enlarged and poorly contracting left ventricle. This 65-year-old man with T2DM, dyslipidemia, and CAD had heart failure due to systolic dysfunction.

In some cases there may be a component of the left ventricular dysfunction that may be reversible with revascularization, and therefore is important to identify. Critical CAD may also impair systolic function due to recurrent ischemia in the absence of frank myocardial necrosis, a process referred to as stunned or hibernating myocardium. In addition, diastolic dysfunction is an important mechanism leading to heart failure in patients with CAD.¹⁵⁹ Impaired left ventricular relaxation and compliance may result from myocardial fibrosis or ischemia and increases left ventricular diastolic pressures.

Hypertension and Heart Failure

Hypertension is the most common cause of heart failure in the absence of CAD,¹⁵⁵ and is present in approximately 40–60% of patients with T2DM.⁴³ In hypertensive patients, diabetes is an independent risk factor for the development of heart failure, increasing the risk 1.8-fold in men and 3.6-fold in women.¹⁶⁰ Thus, the combination of hypertension and diabetes appears to cause heart failure in patients,^{30,161–163} as it does in animal models.^{164–166}

The combination of diabetes and hypertension is also associated with a greater degree of left ventricular hypertrophy (Fig. 49-4) and diastolic dysfunction. In some populations, diabetes has been associated with an increase in left ventricular mass even in the absence of hypertension.^{167,168} Diabetes also increases left ventricular mass in patients with hypertension.^{168a} Indeed hyperinsulinemia and insulin resistance, which are common in T2DM, have been correlated with left ventricular mass.¹⁶⁹ This may be related in part to the action of insulin to decrease the rates of protein breakdown in the heart.¹⁷⁰ In addition, patients with diabetes and hypertension may progress to develop a dilated cardiomyopathy with both systolic and diastolic dysfunction.¹⁶¹ The mechanism responsible for the deterioration in left ventricular systolic function remains uncertain, but once systolic dysfunction becomes established, heart failure can be difficult to treat in these patients.

Diabetic Cardiomyopathy

The diagnosis of diabetic cardiomyopathy is sometimes invoked as the cause of unexplained heart failure or abnormalities in left ventricular function observed in patients with diabetes.

FIGURE 49-4. Left ventricular hypertrophy. Echocardiogram demonstrating the cross-sectional images of a hypertrophied but normally-contracting left ventricle. This 71-year-old woman with T2DM, hypertension, and obesity had heart failure due to diastolic dysfunction.

Pathologic Findings

A specific cardiomyopathy related to diabetes was initially proposed 30 years ago.¹⁷¹ In a small number of patients who died with unexplained heart failure, myofibrillar hypertrophy and diffuse interstitial fibrosis were observed in the absence of significant obstructive CAD. These patients did have diabetic nephropathy, and it is possible that renal insufficiency and undiagnosed hypertension may have contributed to these pathologic findings. Nonetheless, interstitial fibrosis and increased myocardial collagen deposition^{30,162,172} may decrease left ventricular compliance and contribute to diastolic dysfunction in patients with diabetes.

In addition, small-vessel changes may play a role in the pathogenesis of diabetic cardiomyopathy, even in the absence of significant large-vessel atherosclerotic CAD. Perivascular fibrosis,^{29,173,174} thickening of myocardial capillary basement membranes and microaneurysms⁴⁰ have been reported in the diabetic heart. To some extent, these pathologic findings may contribute to the physiologic abnormalities in coronary flow reserve which occur in patients with both type 1³¹ and type 2¹⁷⁵ diabetes in the absence of evident CAD. However, abnormal coronary flow reserve also results from endothelial dysfunction, which is related to glycemic control,¹⁷⁶ lipid levels, and a number of other dynamic factors. These functional abnormalities may be more important than the pathologic findings in determining flow reserve. Indeed, abnormalities in flow reserve appear to be associated with diastolic dysfunction in patients with T2DM.¹⁷⁷ Whether this represents a true causal link or simply an association is unclear.

Abnormalities in Cardiac Function

Several series have reported that patients with T1DM and T2DM have asymptomatic abnormalities in cardiac function. These include alterations in left ventricular systolic function (contraction), diastolic function (relaxation), and the ability of the left ventricle to increase its contractility during exercise. Although the preponderance of evidence supports the notion that these abnormalities are primarily related to diabetes or its complications, all of

these abnormalities can also occur in the presence of underlying hypertension or CAD. In some series, patients with mild hypertension were included in the analysis, and occult CAD was not rigorously excluded, limiting their conclusiveness. In most studies, patients underwent exercise stress testing, and in some they also had myocardial perfusion imaging, but in very few did patients undergo coronary angiography to exclude occult CAD.

With these caveats in mind, abnormalities in resting systolic function have been reported in patients with diabetes. These include prolongation of the left ventricular pre-ejection interval and shortening of the systolic ejection period,¹⁷⁸ diminished fractional shortening and left ventricular ejection fraction,¹⁷⁹ and increased left ventricular systolic dimension and left ventricular mass.^{180,181} However, conflicting information exists, in that other studies have reported decreased fractional shortening in diabetic patients,¹⁸² particularly those with microalbuminuria.¹⁸³ Systolic ejection indices are also influenced by preload and afterload, which can vary with glycemic control. Thus in otherwise healthy diabetic patients, resting abnormalities in systolic function are generally not pronounced.

On the other hand, abnormal augmentation of systolic function during exercise has been more commonly observed in diabetic patients. Impaired augmentation of left ventricular ejection fraction (LVEF) during exercise occurs in up to 40% of diabetic patients including those with T1DM and T2DM.¹⁸⁴⁻¹⁸⁸ Impaired LVEF response has been somewhat variably defined as a decrease, change, or a subnormal increase (<3–5%) in LVEF with exercise and is also influenced by changes in afterload and preload. Interestingly, end-systolic indices of contractility and dobutamine-stimulated left ventricular function may be normal in young diabetic patients who have abnormal exercise ejection fractions. These findings suggest that exercise abnormalities may reflect altered loading conditions or autonomic activation during exercise rather than cardiac muscle dysfunction *per se* in diabetic patients.

Diastolic function abnormalities have been widely documented in patients with diabetes (Fig. 49-5). These include prolonged isovolumic relaxation time,¹⁹⁰⁻¹⁹² delayed opening of the mitral valve

FIGURE 49-5. Diastolic dysfunction. Left ventricular volume measured by radionuclide ventriculography from a healthy control subject and a 37-year-old woman with longstanding T1DM. The curves demonstrate left ventricular emptying during systole (downstroke) and filling during diastole (upstroke). The volume curve from the diabetic patient has a blunted upstroke, which indicates impaired ventricular diastolic filling. The calculated peak diastolic filling rate (PFR) was reduced in the diabetic patient (2.8 volumes/sec) and normal in the control (4.5 volumes/sec).

decreased rate of left ventricular diastolic filling,^{193–195} and abnormal transmitral flow velocities.^{195–199} In addition, radionuclide ventriculography studies have shown that both left ventricular peak filling rate and the time to peak filling were abnormal in T1DM and T2DM.^{187,198,200,201} Diastolic abnormalities may be present earlier than systolic abnormalities in patients with diabetes.²⁰²

These contractile abnormalities may be related in part to hyperglycemia and insulin deficiency. In some studies, abnormalities in ventricular function resolved with improved glycemic control,¹⁹² indicating that the changes in left ventricular hemodynamics and neurohumoral activation associated with hyperglycemia may contribute to alterations in cardiac function. Abnormal cardiac indices have also been shown to correlate with other diabetes complications such as microangiopathy.¹⁹² Cardiac autonomic neuropathy may contribute to the abnormalities in left ventricular function in diabetics^{186,203–205} and will be discussed in more detail below.

Experimental Models

The normal contraction and relaxation of myofibrillar proteins depends on the integrity of the cellular and molecular mechanisms involved in regulating calcium flux, contractile protein function, and substrate and energy metabolism in the heart. Many abnormalities in these essential pathways have been described in experimental animal models of diabetes.^{206–208}

Systolic contraction depends on calcium release from the sarcoplasmic reticulum (SR) interacting with calcium binding proteins that modulate the interaction of actin and myosin filaments. Diastolic relaxation of the heart is also an active process, requiring that the SR removes calcium from the cytosol. In experimental animal models of diabetes, alterations in calcium homeostasis include abnormal sarcolemmal calcium binding,²⁰⁸ decreased calcium pump activity,²⁰⁹ sodium-calcium exchange,²¹⁰ and SR calcium pump activity.^{211,212} A diminished peak, but prolonged increase in intracellular calcium concentration occurs in isolated cardiac myocytes from diabetic rats.²¹³ High extracellular glucose and low insulin concentrations may directly impair relaxation and electromechanical coupling in cultured rat myocytes.^{214,215} Of interest, hyperglycemia increases the activity of the important signaling pathway involving protein kinase C, and transgenic models overexpressing this signaling protein develop cardiomyopathy.²¹⁶

Abnormalities in myofibrillar proteins in the diabetic heart may also contribute to impaired contractile function. A shift to the lower activity V3 isoform of the myosin heavy chain leads to diminished cardiac contractility in rodents.^{217,218} Altered phosphorylation of troponin I and myosin light chain proteins which regulate contractile protein activity may also interfere with function in the diabetic heart.^{219,220} Abnormal collagen crosslinking due to glycosylation products decreases diastolic relaxation.²²¹

There are several additional molecular alterations which may lead to contractile dysfunction in diabetes.^{206–208} However, animal models of diabetes have limitations with respect to their applicability to human disease. Thus more information is needed to understand the pathophysiology of heart failure in patients with diabetes.

Prognosis and Response to Therapy

The presence of diabetes increases the morbidity and mortality in patients with heart failure. In the Framingham study, diabetes was an independent predictor of death in women with heart failure, increasing their mortality 1.8-fold.¹⁵⁵ The Studies of Left Ventricular Dysfunction (SOLVD) demonstrated that diabetes increased the

risk of heart failure, morbidity, and mortality in patients with low ejection fractions.²²² This risk increased with diabetes duration and was also particularly apparent in women. As discussed above, heart failure is an important cause of the higher morbidity and mortality observed in diabetic patients after MI, as well as following coronary revascularization.^{128,223} Thus early detection and management of heart failure are essential for the improvement in clinical outcomes in diabetic patients.

The treatment of heart failure in diabetic patients parallels many of the same strategies utilized in patients without diabetes. The identification and optimal treatment of coexistent hypertension and coronary artery disease is of paramount importance. In the UKPDS, more intensive blood pressure control decreased the incidence of heart failure by 40% in patients with T2DM.²²⁴ Blood pressure should be lowered to below 130/80, and even more aggressive lowering of blood pressure is often indicated to reduce afterload and reverse left ventricular hypertrophy when present.

ACE Inhibitors

ACE inhibitors have a well-established role in the treatment of heart failure. In diabetic patients with reduced systolic function (low LVEF), ACE inhibitors reduce the number of hospitalizations for heart failure and decrease mortality.²²² There are no studies proving the utility of ACE inhibitors in the treatment of heart failure due to diastolic dysfunction (normal LVEF). However, the actions of ACE inhibitors to reduce afterload, decrease neurohumoral responses, and reduce left ventricular mass are all important in the treatment of heart failure due to diastolic dysfunction. In addition, the recent Heart Outcomes Prevention Evaluation (HOPE) study supports the use of ACE inhibitors to decrease cardiac events in diabetic patients, even in the absence of heart failure or known low ejection fractions.⁶¹ Thus in the absence of a clear contraindication (angioedema, severe cough, bilateral renal artery stenosis, or significant hyperkalemia), these drugs should be part of the standard treatment of heart failure in diabetic patients.

Beta-Blockers

Beta-adrenergic receptor blockers are useful in the long-term treatment of patients with heart failure. They are administered after the patient has been stabilized on ACE inhibitors, diuretics, and digoxin, but are contraindicated when overt pulmonary congestion or hypotension are present. Many diabetic patients with heart failure have an underlying ischemic cardiomyopathy, and treatment with beta-blockers clearly improves outcomes in diabetic patients after MI.^{137,138} In the overall population with chronic heart failure and systolic dysfunction, beta-blockers also improve left ventricular function, prevent heart failure symptoms, and increase survival.^{225,226} A preliminary report on the diabetic patients in the Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF), indicates that beta-blockers decrease hospitalization for heart failure and mortality in individuals with class II–III heart failure.²²⁷ Although there are some concerns about potential worsening of glycemic control in T2DM and masking hypoglycemic symptoms in patients receiving insulin, these drugs are generally recommended for diabetic patients with heart failure.

Diuretics

Diuretics are an essential part of the treatment of patients with symptomatic heart failure. In addition to loop diuretics, recent evidence from the Randomized Aldactone Evaluation Study (RALES)

indicates that the aldosterone antagonist spironolactone may have an important role in the treatment of advanced symptomatic heart failure.²²⁸ Treatment with spironolactone reduced hospitalizations for heart failure and cardiac mortality. Although this drug is generally used with caution in patients with diabetes or renal insufficiency due to concern for hyperkalemia, there was no increase in the incidence of dangerous hyperkalemia in diabetic patients treated with this medication.²²⁹

Calcium Channel Blockers

Diastolic dysfunction is an important cause of heart failure in diabetic patients. Calcium channel blockers theoretically may decrease intracellular calcium and improve diastolic relaxation in patients with heart failure due to diastolic dysfunction. However, there is little clinical evidence that these agents are specifically useful in treating diastolic dysfunction. The primary approaches to treat heart failure due to diastolic dysfunction include intensive treatment of hypertension (to reduce afterload and left ventricular mass) and diuretics (to prevent volume overload). In this regard, calcium channel blockers are often useful in treating hypertension in T2DM patients. However, in patients who have heart failure with significant systolic dysfunction, diltiazem and verapamil are contraindicated. In patients who have systolic dysfunction and remain hypertensive despite treatment with an ACE inhibitor, beta-blocker, and diuretic, long-acting dihydropyridine antagonists are often helpful.

Cardiac Transplantation

When conventional heart failure treatment fails in an otherwise healthy diabetic patient with advanced cardiomyopathy, consideration is given for cardiac transplantation. Although insulin-requiring diabetes was once a contraindication to heart transplantation, this is no longer the case at most centers, since the overall survival in the absence of end-organ disease is comparable to those without diabetes. However, end-organ disease, especially nephropathy, increases the risk of unfavorable clinical outcomes after heart transplantation. Diabetic subjects typically require high doses of insulin and other adjuvant hypoglycemic agents during the early phases after transplantation when they are on high doses of corticosteroids.

Diabetes is a risk factor for significant cardiac transplant rejection,²³⁰ although this is a relatively rare occurrence with the use of current immunosuppressive therapies. However, insulin resistance and dyslipidemia increase the risk for transplant vasculopathy, which is the major threat to the transplanted heart.²³¹ Diabetes also accelerates the development of transplant vasculopathy in animal models.²³² Aggressive lipid-lowering with statins is important to reduce the development of transplant vasculopathy.²³³ However, all patients with T2DM require careful surveillance for the development of vasculopathy following heart transplant.

CARDIAC AUTONOMIC NEUROPATHY

Cardiac autonomic neuropathy develops over time in 6–21% of patients with T1DM and in 16–22% of patients with T2DM.^{234–240} The reported prevalence rates have varied widely as a result of different methods and criteria used to diagnose autonomic neuropathy. In the DCCT, the prevalence of autonomic neuropathy was 6% in patients with T1DM.²⁴¹ In the Oxford Community Diabetes Study, the prevalence of autonomic neuropathy was 16% in T2DM.²⁴⁰

Autonomic neuropathy may involve the parasympathetic and sympathetic innervation of the heart and peripheral vasculature leading to a spectrum of manifestations. In its mildest form, cardiac neuropathy involves the parasympathetic innervation of the heart and may lead to a slightly increased resting heart rate. In advanced cases, autonomic neuropathy causes severe orthostatic hypotension with recurrent lightheadedness, unsteadiness, or syncope.

Diagnosis

The diagnosis of cardiac autonomic neuropathy often requires specific autonomic testing. The standard approach involves analysis of changes in heart rate and blood pressure during provocative maneuvers. These include measuring changes in heart rate during deep breathing, standing, and Valsalva maneuvers, along with blood pressure responses to hand grip and standing. The reliable diagnosis of cardiac autonomic neuropathy requires that the procedures are performed in a standardized manner. The test results may be influenced by a number of factors, including recent meals, insulin administration, caffeine, alcohol, smoking, and medications.²⁴²

Analysis of heart rate variability provides an important approach to the assessment of cardiac autonomic function in the patient with diabetes.^{234,243–245} The instantaneous heart rate (R-R interval) varies due to the influence of both parasympathetic and sympathetic modulation. The variability in R-R intervals can be assessed by using either statistical analysis of R-R interval change (time-domain) or spectral analysis of successive R-R interval (frequency-domain). The latter approach differentiates to some extent between sympathetic and parasympathetic influences based on the frequency of the heart rate variability. Variations that occur in the high frequency range (0.15–0.40 Hz) are modulated more by parasympathetic activity, while low frequency (0.04–0.15 Hz) variability is modulated more by sympathetic activity. Recently, autonomic analyses have been incorporated into clinical monitoring systems which should facilitate the diagnosis of diabetic autonomic neuropathy.^{245a}

Cardiac imaging with radiolabeled ¹²³I-meta-iodobenzylguanidine (MIBG) has also been utilized investigatively to assess the integrity of cardiac sympathetic innervation. Cardiac imaging is performed with single photon emission computed tomography (SPECT), which determines the uptake of the tracer by different regions of the heart. Abnormalities in MIBG uptake in patients with T2DM tend to involve the inferoposterior region of the left ventricle.²⁴⁶ In type 1 diabetics, MIBG abnormalities are also observed even in the absence of abnormalities in heart rate variability.^{247,248} More recently, heart sympathetic integrity has been assessed by determining the uptake of ¹¹C-ephedrine using positron emission tomography.²⁴⁹ This approach has demonstrated heterogeneity in myocardial uptake of ¹¹C-ephedrine with diminished activity in the distal inferior and lateral walls.²⁵⁰

Significance

Cardiac autonomic neuropathy is a marker of cardiovascular risk in patients with known cardiac disease as well as in diabetics. Early studies demonstrated 5-year mortality rates of 50% in diabetics with symptomatic cardiac autonomic neuropathy.²⁵¹ However, more recent evidence indicates a somewhat better prognosis, with mortality rates of ~25%.^{252,253} It has been theorized that cardiac neuropathy creates an autonomic imbalance, predisposing to arrhythmic events,²⁵⁴ or interferes with the perception of angina

predisposing to severe ischemia.⁵⁴ However, these concepts remain unproven and cardiac autonomic neuropathy may be associated with other factors predisposing to cardiac events, or to severe CAD or prior MI. Interestingly, cardiac autonomic dysfunction is related to poor glycemic control^{241,255} and abnormal lipid levels.²⁵⁶ The exact mechanism by which autonomic neuropathy contributes to cardiovascular mortality remains uncertain. However, a high level of attention is warranted in diabetic patients with cardiac neuropathy, in whom the presence of significant CAD should be considered.

Cardiac autonomic dysfunction has adverse physiologic consequences, compromising exercise capacity and left ventricular contractile reserve. Peak heart rate and blood pressure responses to exercise are blunted in diabetics with autonomic neuropathy.²⁵⁷ In addition, peak exercise left ventricular ejection fraction¹⁸⁴⁻¹⁸⁶ and diastolic relaxation are sometimes impaired.²⁰⁰ These abnormalities occur in the absence of detectable CAD and hypertension. In one study, more than 90% of diabetic patients with exercise-induced systolic dysfunction had cardiac autonomic dysfunction, and more than half of diabetic patients with cardiac autonomic neuropathy had systolic dysfunction.¹⁸⁶ Patients with T1DM who have abnormal contractile reserve also often have abnormal MIBG imaging, indicating abnormal cardiac sympathetic innervation.²⁵⁸

Cardiac autonomic neuropathy has been invoked as a potential mechanism of sudden death in patients with diabetes. A number of studies have correlated autonomic neuropathy with prolongation of the QT interval.^{259,260} However, few of the patients in these studies have frankly pathologic QT prolongation. QT dispersion reflecting interlead variability in the QT interval may also occur more frequently in individuals with diabetes and autonomic neuropathy.^{261,262}

Cardiac autonomic neuropathy may also have a role in the pathogenesis of silent ischemia in patients with diabetes (see above discussion). Early studies showed a high incidence of asymptomatic ischemia in diabetics with cardiac autonomic dysfunction.⁵⁴ These patients also have abnormalities in cardiac MIBG uptake.⁴⁷ However, silent ischemia during exercise occurs in a substantial number of patients without diabetes or autonomic dysfunction.^{44,50,263} Thus the mechanisms responsible for silent ischemia are complex and may involve central as well as autonomic pathways that are currently under investigation.

CONCLUSION

The association between diabetes and heart disease has been recognized for over 100 years. However, in contrast to the overall population, progress in reducing heart disease morbidity and mortality has lagged behind in patients with diabetes.²⁶⁴ With this recognition, there have been recent efforts to better define the pathophysiology and treatment of heart disease in patients with diabetes. Ongoing research studies promise to answer key clinical questions related to how best to identify and treat CVD in patients with diabetes.

Peripheral Vascular Disease in the Person with Diabetes

Cameron M. Akbari

Frank W. LoGerfo

Diabetes mellitus is found in over 6% of the U.S. population, and the incidence is rising, with more than half a million new cases diagnosed annually.¹ Many epidemiologic studies spanning several decades have clearly established the link between diabetes and vascular disease. The Framingham Study of over 5000 subjects demonstrated that diabetes is a powerful risk factor for atherosclerotic coronary and peripheral arterial disease, independent of other atherogenic risk factors, with a relative risk averaging twofold in men and threefold for women.² The Framingham Study also confirmed that the risk of stroke is at least 2.5-fold higher in patients with diabetes,³ a finding that has been confirmed in other large epidemiologic studies.^{4,5} Moreover, diabetes is strongly associated with atherosclerosis of the extracranial internal carotid artery and thus imparts an additional independent risk of stroke.⁶

PATHOPHYSIOLOGY

The complications of diabetes may best be characterized as alterations in vascular structure and function, with subsequent end-organ damage and death.⁷ Specifically, two types of vascular disease are seen in patients with diabetes: a nonocclusive microcirculatory impairment involving the capillaries and arterioles of the kidneys, retina, and peripheral nerves, and a macroangiopathy characterized by atherosclerotic lesions of the coronary and peripheral arterial circulation.^{8–11} The former is relatively unique to diabetes, whereas the latter lesions are morphologically and functionally similar in both nondiabetic and diabetic patients.

Retinopathy is the most characteristic microvascular complication of diabetes, and population-based studies have identified a correlation between its development and the duration of diabetes.¹² Similar correlations have been found with nephropathy, neuropathy, and diabetes,¹³ with perhaps the strongest evidence coming from the Diabetes Control and Complications Trial (DCCT). The results from the DCCT clearly showed a delay in the development and progression of these microvascular complications with intensive glycemic control, thus supporting the direct causal relationship between hyperglycemia, diabetes, and its microvascular sequelae.¹⁴ These and other clinical trials have provided the rationale for experimental studies investigating the fundamental pathophysiology of micro- and macrovascular disease in diabetes mellitus.

Microvascular dysfunction in diabetes is manifested by an increased vascular permeability and impaired autoregulation of blood

flow and vascular tone. These changes culminate in nephropathy, retinopathy, and neuropathy and probably contribute to the cardiovascular complications of diabetes. Although multiple theories have been postulated as to the etiology of accelerated microangiopathy, it is likely that several biochemical derangements exist in the presence of hyperglycemia and diabetes and that these mechanisms work synergistically to cause microvascular dysfunction. These metabolic alterations produce functional and structural changes in many areas at the arteriolar and capillary levels, including the basement membrane,⁹ the smooth muscle cell,¹⁵ and, in particular, the endothelial cell.¹⁶

One of the greatest impediments in understanding and treating vascular disease in patients with diabetes is the misconception that they have an untreatable occlusive lesion in the microcirculation, which has fostered the belief that arterial reconstruction is futile. This idea originated from a retrospective histologic study demonstrating the presence of PAS-positive material occluding the arterioles in amputated limb specimens from diabetic patients.¹⁷ However, subsequent prospective anatomic staining and arterial casting studies^{18,19} have demonstrated the *absence* of an arteriolar occlusive lesion. Further evidence comes from physiologic studies of femoro popliteal bypass grafts in diabetic and nondiabetic patients in which direct vasodilator administration into these grafts demonstrates a comparable fall in peripheral resistance between the two groups.²⁰ Dispelling the notion of "small vessel disease" is fundamental to the principles of limb salvage in patients with diabetes, since arterial reconstruction is almost always possible and successful in these patients.

Although there is no occlusive lesion in the diabetic microcirculation, other structural changes do exist, most notably thickening of the capillary basement membrane. This alteration in the extracellular matrix may represent a response to the metabolic changes related to diabetes and hyperglycemia. However, these changes do not lead to narrowing of the capillary lumen, and arteriolar blood flow may be normal or even increased despite these changes.²¹ Capillary basement membrane thickening is the dominant structural change in both diabetic retinopathy and neuropathy. In the kidney, nonenzymatic glycosylation reduces the charge on the basement membrane, which may account for transudation of albumin, an expanded mesangium, and albuminuria.²² Similar increases in vascular permeability occur in the eye and probably contribute to macular exudate formation and retinopathy.

In the diabetic foot, basement membrane thickening may theoretically impair the migration of leukocytes and the hyperemic

response following injury and thus may increase the susceptibility of the diabetic foot to infection.^{23,24} Although resting total skin microcirculatory flow is similar in both diabetic and nondiabetic patients, the capillary blood flow is reduced in diabetes, indicating a maldistribution and functional ischemia of the skin.²⁵ Moreover, studies of skin microvascular flow have demonstrated a reduced maximal hyperemic response in diabetic patients, suggesting that a *functional* microvascular impairment is a major contributing factor for diabetic foot problems. All of these changes result in an inability to vasodilate and achieve maximal blood flow following injury.

Diabetes also affects the axon reflex (Fig. 50-1). Injury directly stimulates nociceptive C fibers, which results in both orthodromic conduction to the spinal cord and antidromic conduction to adjacent C fibers and other axon branches. One function of this axon reflex is the secretion of several active peptides, such as substance P and calcitonin gene-related peptide, which directly and indirectly (through mast cell release of histamine) cause vasodilation and increased permeability. This neurogenic vasodilatory response is impaired in diabetes, further reducing the hyperemic response when it is most needed, that is, under conditions of injury and inflammation.²⁶

The above changes contribute to an early functional impairment in vascular reserve in the peripheral, coronary, and cerebral circulation of patients with diabetes. Using positron emission tomography (PET), myocardial blood flow may be measured at rest and after vasodilator administration, and thus coronary flow reserve (as a measure of endothelial function) may be calculated. Reduced coronary flow reserve and impaired coronary reactivity have been observed in diabetic patients with angiographically normal coronary arteries and no other detectable microvascular complications, suggesting an early endothelial dysfunction.^{27,28} Similarly, cerebrovascular reactivity and reserve capacity may be assessed using transcranial Doppler and acetazolamide, which causes vasodilation of the brain resistance vessels. Impaired cerebrovascular reserve is

also noted in patients with diabetes, particularly among those patients with other microvascular complications.²⁹

There is substantial evidence that endothelial function is abnormal in animal models of diabetes mellitus³⁰⁻³² and in patients with both type 1 and type 2 diabetes mellitus (T1- and T2DM),^{33,34} thus directly implicating either hyperglycemia or hyperinsulinemia as a possible mediator of abnormal endothelium-dependent responses. A variety of mechanisms responsible for vascular dysfunction have been proposed, principally abnormalities in the nitric oxide pathway, abnormal production of vasoconstrictor prostanoids, intracellular signaling, reduction in Na^+/K^+ -ATPase activity, and advanced glycosylated end products.³⁵⁻³⁷

In 1980, Furchgott and Zawadzki³⁸ discovered that arterial vasodilation was dependent on an intact endothelium and its release of a substance they called endothelium-derived relaxing factor (EDRF), which causes arterial smooth muscle relaxation in response to acetylcholine and other vasodilators. Later identified as endothelial-derived nitric oxide (EDNO), it activates vascular smooth muscle guanylate cyclase, elevates cyclic GMP levels, and may increase Na^+/K^+ -ATPase activity.³⁹

A variety of substances other than acetylcholine may cause EDNO-mediated vasodilation. Notably, it appears that the vasodilatory effects of insulin are nitric oxide-dependent^{40,41} and that insulin mediates vasodilation by modulating the synthesis and release of EDNO. Although hyperglycemia with hyperinsulinemia impairs endothelial-dependent vasodilation, hyperinsulinemia with euglycemia actually potentiates endothelium-dependent vasodilation via enhanced EDNO release, suggesting that hyperglycemia, independent of hyperinsulinemia, contributes to endothelial dysfunction. This has been corroborated by studies performed on healthy individuals, in which ingestion of a glucose load and subsequent acute hyperglycemia impair the endothelial-dependent vasodilation of the macrocirculation and microcirculation.⁴²

FIGURE 50-1. Illustration of the axon (nociceptive) reflex, in which injury results in vasodilation via secretion of active peptides such as substance P, histamine, and calcitonin gene-related peptide.

Impaired endothelial-dependent vasodilation in certain insulin-resistant states may be instrumental in the pathogenesis of atherosclerosis and hypertension and is postulated to be due to diminished insulin-mediated EDNO production and release.⁴³ Patients with T1- and T2DM demonstrate impaired endothelium-dependent responses to acetylcholine, but the response to exogenous nitric oxide donors (i.e., sodium nitroprusside) remains intact in T1DM^{32,33} (Fig. 50-2).

Although there is considerable controversy regarding the role of free radicals in diabetic vascular disease,⁴⁴ an increased production of oxygen-derived free radicals has been described in diabetes and may contribute to endothelial dysfunction.⁴⁵ Superoxide anions and other oxygen-derived free radicals directly inactivate EDNO.⁴⁶ In animal models, endothelium-derived free radicals impair EDNO-mediated vasodilation, and administration of superoxide dismutase and other free radical scavengers normalizes EDNO-dependent relaxation in diabetic arteries.⁴⁷ Defective endothelium-dependent relaxation in diabetic rat aorta is significantly attenuated by vitamin E, a potent free radical scavenger.⁴⁸ In human studies, administration of vitamin C in pharmacologic doses restores and improves endothelium-dependent vasodilation, but not endothelium-independent responses in patients with both T1- and T2DM, thus further suggesting that oxygen-derived free radicals may decrease the bioavailability of EDNO.⁴⁹

A potentially treatable source of oxygen-derived free radicals is hyperlipidemia. Increased levels of low-density lipoprotein (LDL) and very-low-density lipoprotein (VLDL) are common in diabetic patients. Hyperglycemia promotes the oxidation and nonenzymatic glycation of LDL, which has been strongly implicated in atherogenesis by a variety of mechanisms.⁵⁰ In animal models of hypercholesterolemia, the vascular endothelium produces several free radicals, presumably through xanthine oxidase activation, and these endothelial-derived free radicals inactivate EDNO.⁵¹ Moreover, flow-mediated vasodilation and reactive hyperemia (endothelium-dependent) are more impaired in patients with T1DM and elevated LDL cholesterol levels, which further supports the relationship of hypercholesterolemia, free radicals, and EDNO.⁵²

FIGURE 50-2. In response to acetylcholine, nitric oxide synthetase (NOS) is activated, which leads to nitric oxide (NO) release and vasodilation. The response is endothelium-dependent in that it is dependent on endothelium-derived NOS and NO. In contrast, sodium nitroprusside, an exogenous nitric oxide donor, directly activates cyclic guanosine monophosphate (cGMP) and thus is not dependent on endothelium-derived NOS and NO. TXA₂, thromboxane A₂; PGs, prostaglandins. (Reproduced from Akbari et al.⁷)

Advanced glycosylation end products (AGEs) have also been implicated in the pathogenesis of diabetic microvascular complications. These are formed from a reversible reaction between glucose and protein to form Schiff bases, which then rearrange to form stable Amadori-type early glycosylation products. Some of these reversible early glycosylation products may undergo complex arrangements to form irreversible AGEs. In experimental diabetes AGEs impair the actions of EDNO and cause an impaired endothelium-dependent response, which is ameliorated by administration of an AGE inhibitor.⁵³

AGEs also displace disulfide cross-linkages in collagen and scleral proteins, accounting for the diminished charge in the capillary basement membrane. This may contribute to the increased vascular permeability of diabetes, since blockade of a specific receptor for AGE reverses diabetes-mediated vascular hyperpermeability. Moreover, the presence of AGE receptors on both endothelial cells and monocytes, along with AGE deposition in the subendothelium suggests monocyte deposition into the subendothelial space as a secondary complication.⁵⁵ In studies using a radioreceptor assay for AGEs in serum and arterial wall, higher AGE levels have been demonstrated in patients with diabetes compared to nondiabetic controls, with the highest levels occurring among diabetic patients with nephropathy.⁵⁶ Since at least part of AGE-induced cellular dysfunction is due to an oxidant-sensitive mechanism, which is inhibited by antioxidants, it is likely that both oxygen-derived free radicals and AGEs contribute to cause impaired EDNO-dependent vasodilation in diabetes. Taken together, the effects of AGEs on vascular permeability, subendothelial protein deposition, inactivation of nitric oxide, and modification of LDL provide strong evidence of their important role in diabetic vascular disease.

Experimental studies in diabetic animals have also indicated that abnormal endothelial production of vasoconstrictor prostanooids, notably thromboxane (TX) A₂ and prostaglandin (P) H₂, may contribute to endothelial cell dysfunction. In humans, however, the role of vasoconstrictor prostanooids is less clear. Flow-dependent vasodilation in healthy subjects, which may be used as an index of endothelial function, is unaffected by aspirin, thus demonstrating that it is entirely mediated by EDNO and independent of vasoactive prostanooids.⁵⁷ Moreover, the attenuated endothelium-dependent vasodilation that is observed in diabetic patients following acetylcholine administration is not affected by pretreatment with cyclo-oxygenase inhibitors.

It therefore appears that dysfunction of the microcirculation strongly contributes to the renal, eye, and macrovascular complications of diabetes. Several lines of evidence have indicated that the microcirculation is also implicated in the pathogenesis of diabetic neuropathy, and the etiology of diabetic neuropathy may be a complex interplay among metabolic and microvascular defects involving aldose reductase, Na⁺/K⁺-ATPase activity, and nitric oxide. Some of these may include EDNO stimulation of Na⁺/K⁺-ATPase activity, decreased Na⁺/K⁺-ATPase activity by EDNO inhibitors, and hyperglycemic inhibition of Na⁺/K⁺-ATPase activity in normal rabbit aorta, which is preventable by administering aldose reductase inhibitors or by raising plasma myoinositol levels.^{58,59}

More recent studies using laser Doppler imaging have further defined the relationships among the microcirculation, diabetes, and neuropathy.⁶⁰ These findings suggest that the endothelium-dependent vasodilation and the axon reflex are impaired in the presence of diabetes and neuropathy but that the endothelium-independent response is spared, and that this dysfunction may

attributed to an impaired production of nitric oxide. In addition, the nerve axon reflex is reduced in diabetic neuropathic patients with and without vascular disease, while it is intact in diabetic patients without neuropathy. In addition, the expression of endogenous endothelial nitric oxide synthetase (eNOS) activity (taken from the skin of the foot) has been found to be reduced in patients with diabetes and either neuropathy or macrovascular disease, compared with healthy controls.⁶¹ In contrast, the level of von Willebrand factor (an anatomic marker of the endothelium) is comparable among the controls and diabetic patients. Therefore, it appears that in diabetic neuropathic patients, with or without lower extremity ischemia, the eNOS activity is reduced, even though the endothelium is anatomically present and endothelial functional changes may be related to the development of neuropathy.

Current hypotheses regarding the etiology of diabetic neuropathy are centered on a combination of metabolic defects secondary to hyperglycemia and vascular changes that result in nerve hypoxia.⁶² Evidence for a hypoxic etiology is considerable and includes reduced endoneurial blood flow, increased vascular resistance, and decreased endothelial production of nitric oxide.^{63,64} Although microvascular dysfunction has been mainly implicated, the role of peripheral vascular disease remains considerable, as it appears likely that a decrease in total limb blood flow would potentiate nerve ischemia. This concept has been supported by clinical trials, which have demonstrated a more severe neuropathy in diabetic patients with lower limb ischemia compared with non-ischemic diabetic and ischemic nondiabetic patients, and an improvement in nerve function shortly after revascularization.^{65,66}

Clinical studies from the authors' laboratory have focused on the effect of arterial reconstruction on the natural history of diabetic neuropathy.⁶⁷ Fifty-five patients with diabetes and peripheral vascular disease requiring revascularization were studied. Peroneal nerve conduction velocity was measured prior to arterial bypass and then again at a mean follow-up of 19 months. In the operated leg, the peroneal nerve conduction velocity remained unchanged during the follow-up period (preoperative 35.79 ± 6.02 m/s versus postoperative 35.33 ± 7.51 m/s, $p = \text{NS}$), but deteriorated in the nonoperated leg (36.68 ± 6.22 m/s versus 33.64 ± 7.30 m/s, $p < 0.05$). The data suggest that reversal of hypoxia in diabetic patients halts the progression of neuropathy, lending further support to the role of localized ischemia in the pathogenesis of nerve dysfunction in diabetes mellitus.⁶⁸

DIABETES AND CEREBROVASCULAR DISEASE

Compelling data from several large clinical studies have demonstrated that diabetes is a major risk factor for stroke, and the incidence of ischemic stroke is at least 2.5-fold higher in diabetic patients.³⁻⁵ Moreover, the mortality and severity of stroke are higher among patients with diabetes.^{69,70} The relative risk of stroke increases even further among diabetic patients with established retinopathy, neuropathy, or nephropathy, thus suggesting that the presence of diabetes introduces additional microvascular and cerebrovascular pathophysiology, which may increase the frequency and severity of stroke in these patients.^{71,72}

Elevated blood glucose is toxic to infarcted brain tissue, and stroke severity is greater in patients with hyperglycemia.^{73,74} Among patients with diabetes, poor glycemic control doubles the risk of ischemic stroke, even after adjustment for other variables.⁷⁵

Morphologic abnormalities in diabetes include arterial endothelial cell necrosis and thickened capillary basement thickening in cerebral vessels; in addition, diabetic patients have shown impaired cerebrovascular reactivity to hypercapnia and blood pressure changes.⁷⁶ Abnormal cerebral blood flow may be seen in experimental diabetes, and among patients with diabetes and no history of cerebrovascular disease, single-photon emission computed tomography (SPECT) scanning has demonstrated multiple subclinical alterations in cerebral blood flow.⁷⁷ Hyperglycemia alone causes both a decrease in cerebral blood flow and an impaired cerebral vasodilatory response.⁷⁸ As noted previously, altered cerebral vascular reactivity occurs among patients with long-standing diabetes and may reflect a generalized cerebrovascular microangiopathy involving the brain resistance arterioles.²⁸

Acute hyperglycemia and glucose exposure may also impair the autoregulation of cerebral blood flow. *In vitro* exposure of isolated cerebral arteries to high glucose concentrations causes vasodilation and inhibition of arterial tone, suggesting that both cerebrovascular tone and control of cerebral blood flow may be impaired during acute hyperglycemia.⁷⁹ Moreover, since removal of the endothelium abolishes this effect, this appears to be an endothelium-dependent and nitric oxide-mediated mechanism. Impaired cerebral vessel endothelium-dependent relaxation, but not endothelium-independent vasodilation, has also been observed in the presence of diabetes.^{80,81} These findings suggest either reduced activity/synthesis of EDNO or increased destruction, the latter possibly mediated by a thromboxane A₂ and prostaglandin H₂ pathway.

Multiple cerebrovascular metabolic abnormalities also contribute to the worse stroke outcome in hyperglycemia and diabetes.⁸² Anaerobic metabolism of glucose during ischemia produces lactate, which accumulates inside brain cells and results in lower intracellular pH and may promote cell death. As noted earlier, AGEs accumulate as a consequence of diabetes and may also contribute to the increased stroke severity in diabetic patients, as systemic administration of AGEs into animals with focal brain infarction increases cerebral infarct size and damage.⁸³

Because of the worse prognosis of stroke in patients with diabetes, efforts should be directed toward reducing the risk of stroke in these patients, including reduction or elimination of concomitant risk factors. In addition, among selected symptomatic and asymptomatic patients with a high-grade internal carotid artery stenosis, carotid endarterectomy has been shown to reduce the risk of stroke.^{84,85} Because diabetes is associated with multiple cerebrovascular abnormalities, the safety of carotid endarterectomy in patients with diabetes may be questioned.⁸⁶ A recent report has summarized the experience with carotid endarterectomy in patients with diabetes.⁸⁷ Over a 6-year period, 732 carotid endarterectomy procedures were performed, of which 284 (39%) were in patients with diabetes mellitus. The total operative mortality rate was 0.3%. There were 11 perioperative neurologic events (8 strokes, 3 transient ischemic attacks) during the entire period (1.5%), of which 6 (2.1%) were among diabetic patients and 5 (1.1%) among nondiabetic patients, a difference that was not statistically significant. Of the 8 strokes, 3 occurred in diabetic patients (1.0%) and 5 in nondiabetic patients (1.1%), which again was not statistically significant. Moreover, it was demonstrated that diabetes is not an independent risk factor for postoperative cardiac morbidity among patients undergoing carotid endarterectomy. These results show that carotid endarterectomy may be safely performed in diabetic patients, with neurologic morbidity and mortality rates comparable to those of the nondiabetic population.

THE DIABETIC FOOT

Problems of the diabetic foot are the most common cause of hospitalization in diabetic patients, with an annual health care cost of over \$1 billion.⁸⁸ Diabetes is a contributing factor in half of all lower extremity amputations in the United States, and the relative risk for amputation is 40 times greater in people with diabetes.⁸⁹ Diabetic foot ulceration will affect 15% of all diabetic individuals during their lifetime and is clearly a significant risk factor in the pathway to limb loss.⁹⁰ The principal pathogenetic mechanisms in diabetic foot disease are neuropathy, infection, and ischemia; acting together, they contribute to the sequence of tissue necrosis, ulceration, and gangrene (Fig. 50-3).

As discussed previously, the etiology of diabetic neuropathy is unknown and most likely multifactorial. Peripheral neuropathy is a common complication of diabetes, afflicting as many as 50–60% of all patients,^{91,92} and is present in over 80% of diabetic patients with foot lesions, thus further emphasizing the direct relationship between neuropathy and foot ulceration.⁹³ Neuropathy is broadly classified as focal or diffuse; the latter is more common and includes the autonomic and chronic sensorimotor polyneuropathy, which both contribute to foot ulceration.

Sensorimotor neuropathy initially involves the distal lower extremities, progresses centrally, and is typically symmetric. Sensory nerve fiber involvement leads to loss of the protective sensation of pain, whereas motor fiber destruction results in small muscle

FIGURE 50-3. The biologically compromised foot. Multiple abnormalities, including sensorimotor neuropathy, altered architecture, microvascular dysfunction, ischemia, and infection contribute to the diabetic foot. (Reproduced from Akbari et al.⁷)

atrophy in the foot. Consequently, the metatarsals are flexed, with metatarsal head prominence and "clawing" of the toes. This causes abnormal pressure points to develop on the bony prominences without sensation, with subsequent callus formation, cracking, erosion, and ulceration. Meanwhile, autonomic neuropathy in the foot causes loss of sympathetic tone, which results in increased arteriovenous shunting and inefficient nutrient flow. Autonomic denervation of oil and sweat glands leads to cracking of dry skin, which further predisposes the diabetic foot to skin breakdown and ulceration.⁹⁴

The spectrum of infection in diabetic foot disease ranges from superficial ulceration to extensive gangrene with fulminant sepsis (Fig. 50-4). Most infections are polymicrobial, with the most common pathogens being staphylococci and streptococci; more complicated ulcers may harbor anaerobes and gram-negative bacilli. Potential sources of diabetic foot infection include a simple puncture wound or ulcer, the nail plate, and the interdigital web space. Untreated infection can lead to bacterial spread along tendon sheaths and fascial planes, destruction of the interosseous fascia, and spread to the foot dorsum. Edema in the foot elevates compartmental pressures, with resultant capillary thrombosis and further impairment of nutrient blood flow.

Classical signs of infection may not always be present in the infected diabetic foot due to the consequences of neuropathy, alterations in the foot microcirculation, and leukocyte abnormalities. Fever, chills, and leukocytosis may be absent in up to two-thirds of diabetic patients with extensive foot infections, and hyperglycemia is often the sole presenting sign.⁹⁵ Therefore, a complete examination of the infected areas is mandatory, and the wound should be thoroughly inspected, including unroofing of all encrusted areas, to determine the extent of involvement. Because most infections are polymicrobial, cultures should be obtained from the base or depths of the wound after debridement so that appropriate antibiotic treatment may ensue.

Osteomyelitis is common in diabetic foot ulceration and may be demonstrated by bone biopsies in almost 70% of benign-appearing

ulcers.⁹⁶ A variety of diagnostic tests may be ordered to assist in the diagnosis, including plain radiographs, a three-phase bone scan, labeled leukocyte scans, CT scans, and magnetic resonance imaging. Criticism may be leveled at the indiscriminate use of these tests and a costly "shotgun" approach to the diagnosis of osteomyelitis. A more cost-effective approach involves the use of a sterile probe to detect bone in an open ulcer.⁹⁷ With a positive predictive value of nearly 90%, osteomyelitis should be presumed if bone is palpated on probing, thus rendering other specialized and expensive radiographic tests unnecessary.

A critical step for limb salvage in patients with diabetic foot ulceration is a thorough evaluation for ischemia. The complex milieu of motor and sensory neuropathy, capillary basement thickening, loss of the neurogenic inflammatory response, as well as the wide spectrum of microcirculatory and endothelial abnormalities, results in a biologically compromised foot. Even moderate ischemia may lead to ulceration under these circumstances. Thus the concept of ischemia must be modified in making decisions about arterial reconstruction in the diabetic foot, since the biologically compromised foot requires *maximum* circulation to heal an ulcer. This leads to three significant principles: (1) All diabetic foot ulcers should be evaluated for an ischemic component; (2) correction of a moderate degree of ischemia will improve healing in the biologically compromised diabetic foot; and (3) whenever possible, the arterial reconstruction should be designed to restore normal arterial pressure to the target area. Ultimately, all limb salvage efforts will fail unless ischemia is recognized and corrected.

Treatment of the diabetic foot should be directed toward the pathogenic factors outlined above. The most important treatment guidelines are as follows⁹⁸:

1. Prompt control of infection. This assumes first priority in the management of any diabetic foot problem.
2. Evaluation for ischemia.
3. Prompt arterial reconstruction once active infection has resolved.

FIGURE 50-4. Fulminant sepsis in a 52-year-old with an infected diabetic foot. Corresponding x-rays demonstrated gas within the soft tissues (**white arrow**), consistent with a polymicrobial and opportunistic infection. Note the *absence* of cellulitis, due to, among other factors, the consequences of neuropathy and loss of the nociceptive reflex.

4. Secondary procedures, such as further debridement, toe amputations, local flaps, and even free flaps, may then be carried out separately in the fully vascularized foot.

DIABETES AND LOWER EXTREMITY VASCULAR DISEASE

Lower extremity arterial disease is more common among patients with diabetes. The presence of diabetes is associated with a two- to threefold excess risk of intermittent claudication compared with its absence.⁹⁹ Despite significant advances in the prevention and treatment of peripheral vascular disease, diabetes continues to be the single strongest cardiovascular risk factor for the development of critical leg ischemia and limb loss.¹⁰⁰

Unlike microvascular disease, which is unique to diabetes and its metabolic alterations, the cause of lower extremity ischemia is similar in both diabetic and nondiabetic patients and is due to accelerated atherosclerosis. One notable difference between these populations is the pattern and location of the occlusive atherosclerotic lesion. As noted earlier, there is no evidence for an occlusive lesion at the arteriolar level ("small-vessel disease") in patients with diabetes. However, diabetic patients are more likely to have atherosclerotic disease affecting the infrapopliteal (tibial) arteries, with sparing of the foot arteries,¹⁰¹ which allows for successful arterial reconstruction to these distal vessels. Conversely, the superficial femoral or popliteal artery is less likely to be affected by the occlusive process, allowing these vessels to serve as a possible inflow source for bypass grafting.

Because the foot vessels are often patent in the diabetic patient, and because of the success of bypass grafting to these vessels, an appropriate evaluation for ischemia is essential in diabetic patients. Unless ischemia is recognized and corrected, limb salvage efforts with the diabetic foot will fail, even if infection and neuropathy have been appropriately treated.

As with any other disease process, evaluation should begin with a detailed history and physical exam. In the patient with a diabetic foot ulcer, it is helpful to consider the duration of the ulcer, the type of treatments utilized, and any past history of foot ulceration and treatment. Although nocturnal rest pain in the foot is strongly suggestive of lower extremity arterial disease in the nondiabetic patient, the variable effects of neuropathy make pain more difficult to evaluate in the diabetic limb. Similarly, claudication symptoms may be entirely absent in the patient with an ischemic diabetic foot ulcer. Long-standing foot ulceration, coexisting car-

diac disease (such as angina or heart failure), and sensorimotor neuropathy may all limit the ability to ambulate sufficiently to manifest claudication symptoms.

Physical examination should be directed toward the underlying pathophysiology of foot ulceration. Neuropathy may easily be evaluated: Observation may reveal the morphologic motor abnormalities such as "claw foot" or Charcot's osteoarthropathy; monofilament testing will assess the degree of sensory neuropathy. Noting the location of the ulcer may also be helpful, in that purely ischemic lesions typically occur in the most distal parts of the foot such as the toes, forefoot, or heel, in contrast to the neuropathic ulcers seen on the weight-bearing areas.

All ulcers, including those with a significant neuropathic component, should be assessed for an ischemic component. The most important observation is the presence or absence of a palpable foot pulse; in simplest terms, if the foot pulses are not palpable, it can be assumed that occlusive disease is present.

A variety of noninvasive arterial tests may be ordered in an effort to quantify the degree of ischemia. However, in the presence of diabetes, *all* of these tests have significant limitations. Although Doppler-derived pressures have proved to be reliable in localizing the degree and level of arterial occlusive disease in nondiabetic patients, their use is limited in the presence of diabetes. Medial arterial calcinosis occurs frequently in diabetic patients and is characterized by a *nonobstructive* calcification of the vessel wall at the media layer; its presence can result in noncompressible arteries with artifactually high segmental systolic pressures and ankle-brachial indices. Medial calcification should be suspected whenever the ankle pressure greatly exceeds arm pressure or when the Doppler signal at the ankle cannot be obliterated with greater than 250 mm Hg pressure. The finding of lower levels of calcification in the toe vessels supports the use of toe systolic pressures as a more reliable indicator of arterial flow to the foot.¹⁰² However, the use of toe pressures is often limited by the proximity of the foot ulcer to the cuff site, the size of the cuff itself, and other extrinsic variables.

Segmental Doppler waveforms and pulsed volume recordings are unaffected by medial calcification. A normal Doppler waveform is triphasic; with proximal obstruction, the waveform becomes monophasic (Fig. 50-5). Pulse volume recordings rely on plethysmographic recordings of the change in volume that occurs with each pulsation. A sharp upstroke, narrow peak, and dicrotic notch characterize a normal recording. With increasing levels of arterial insufficiency, the waveform loses the dicrotic notch, followed by loss of amplitude and blunting of the waveform (Fig. 50-6). Since neither of these tests relies on obliterating flow within

FIGURE 50-5. The normal Doppler tracing on the left illustrates a triphasic flow pattern, with forward flow in systole (first arrow), a reversal of flow in early diastole (second arrow), and a secondary forward flow in late diastole (third arrow). With proximal arterial obstruction, the waveform becomes monophasic (right), with loss of the reverse flow component and blunting of the systolic peak.

FIGURE 50-6. Normal pulse volume recordings (PVRs) on the left illustrate a brisk, sharp rise to the systolic peak, with a dichrotic notch (indicated by the arrow on the calf tracing). With increasing levels of proximal arterial obstruction (right), the waveform loses the dichrotic notch, the peak becomes more rounded, and the downslope is prolonged. Severe occlusive disease produces a flattened waveform with a slow upstroke and downstroke.

a vessel (unlike Doppler-derived pressures), they may prove useful in the diabetic patient with suspected arterial insufficiency. However, significant limitations exist in their use, and caution should be exercised when interpreting results. Evaluation of these waveforms is primarily qualitative and not quantitative. A flat forefoot tracing is a convincing demonstration of ischemia, but it is difficult to make clinical decisions based on the magnitude of the waveform. Similarly, severity of arterial insufficiency cannot be accurately interpreted, since no reliable quantitative scoring exists. In addition, the quality of the waveforms is affected by peripheral edema, cuff size, and motion artifact. Finally, the presence of ulceration, especially at the forefoot level, often precludes accurate cuff placement.

Regional transcutaneous oximetry (TcPO₂) measurements are also unaffected by medial calcinosis, and recent studies have noted its reliability in predicting healing of ulcers and amputation levels.¹⁰³ Limitations, including a lack of equipment standardization, user variability, and a large "gray area" of values, preclude its applicability. Furthermore, TcPO₂ measurements are higher in diabetic patients with foot ulcers compared with the nondiabetic population, which further limits the ability of this test to predict ischemia.¹⁰⁴

The limitations of noninvasive vascular testing in diabetic patients with foot ulceration emphasize the continued importance of a thorough bedside evaluation and clinical judgment. To reiterate, the status of the foot pulse is the most important aspect of the physical exam. In simplest terms, it can be assumed that occlusive disease is present if the foot pulses are not palpable. This finding alone is an indication for contrast arteriography in the clinical setting of tissue

loss, poor healing, or gangrene, even if neuropathy may have been the antecedent cause of skin breakdown or ulceration.

Concern for contrast-induced renal failure should not mitigate against a high-quality angiogram of the entire lower extremity circulation. The incidence of contrast nephropathy is not higher in the diabetic patient without preexisting renal disease, even with the use of ionic contrast.^{105,106} The more costly nonionic agents should be reserved for the diabetic patient with compromised renal function. Even in this group, the concern for contrast nephropathy should not delay arteriography, as it seldom requires dialysis for treatment. More recently, attention has focused on the roles of magnetic resonance angiography, carbon dioxide angiography, and duplex scanning as replacements for contrast arteriography. However, each has its own limitations, and although we have selectively utilized these modalities, we continue to rely heavily on a high-quality contrast arteriogram for most of our patients requiring distal arterial reconstruction.

Whatever preoperative imaging modality is chosen prior to arterial reconstruction, it is mandatory that consideration be given to the pattern of lower extremity vascular disease in patients with diabetes. Because the foot vessels are often spared by the atherosclerotic occlusive process, even when the tibial arteries are occluded, it is essential that arteriograms not be terminated at the midtibial level. The complete infrapopliteal circulation should be incorporated, including the foot vessels. The advent of digital subtraction angiography, which allows for subtraction of the bones from the final images, has greatly helped in visualizing these distal vessels. Both anteroposterior and lateral foot views should be included to differentiate branch vessels and to visualize all stenoses.

PRINCIPLES OF ARTERIAL RECONSTRUCTION IN THE DIABETIC FOOT

A complete arteriogram will facilitate the choice of an outflow artery that will restore a palpable foot pulse. Proximal bypass to the popliteal or tibioperoneal arteries may restore foot pulses. More often, however, because of the pattern of occlusive disease in the diabetic patient, bypass grafting to the popliteal or even tibial arteries cannot accomplish this goal, due to more distal obstruction. Similarly, although excellent results have been reported with peroneal artery bypass,¹⁰⁷ the peroneal artery is not in continuity with the foot vessels and may not achieve maximal flow, particularly to the forefoot, to achieve healing.

Restoration of the foot pulse is a fundamental goal of revascularization in the diabetic foot. Specifically, autogenous vein grafting to the dorsalis pedis, distal posterior tibial, and plantar arteries incorporates our knowledge of the anatomic pattern of diabetic vascular disease and provides durable and effective limb salvage. The choice of outflow artery should be based on availability of conduit, the location of the foot ulcer, and the quality of the outflow vessel.

The dorsalis pedis bypass represents the single most important advance in our management plan for diabetic limb salvage^{108,109} (Fig. 50-7). Fundamental to the success of the dorsalis pedis bypass are meticulous technique and its appropriate use. The principal indication for the pedal graft is when there is no other vessel that has continuity with the foot, particularly in cases with tissue loss. Dorsalis pedis bypass is unnecessary when a more proximal bypass will restore foot pulses and should not be done if there is an inadequate length of autogenous vein. In addition, if the dorsum of the foot is extensively infected and the peroneal artery is of good quality on the preoperative arteriogram, preference should be given to peroneal artery bypass.

Technical feasibility and short-term durability of dorsalis pedis arterial bypass have been demonstrated, with patency and limb salvage rates approaching 90% at 3 years.¹¹⁰ A more extensive 8-year experience encompassing 384 vein grafts to the dorsalis pedis artery in 367 patients has been reported.¹¹¹ Ninety-five percent of the patients had diabetes mellitus, and all procedures were performed for limb-threatening ischemia. Twenty-nine grafts (7.5%) failed within the first 30 days, but 19 were successfully revised when a correctable technical problem was found at reoperation. The perioperative in-hospital mortality rate was 1.8%, and the actuarial primary and secondary patency rates were 68% and 82% at 5-year follow-up. Furthermore, the limb salvage rate was 87% at 5 years, again attesting to the durability of the dorsalis pedis graft.

The distal location of the dorsalis pedis artery theoretically necessitates a long venous conduit, which is often not attainable. However, by using the popliteal or distal superficial femoral artery as an inflow site, a shorter length of vein may be used, with excellent long-term patency.¹¹² This is particularly true in the diabetic patient, again due to the pattern of atherosclerotic disease. In the authors' institutional experience of 384 pedal bypasses over a 7-year period, 60% of grafts utilized the more distal inflow site, usually the popliteal artery. This avoids dissection in the groin and upper thigh, a common location for wound complications, and also obviates the need for foot extension of the vein harvest incision. The approach is flexible, in that the vein graft to the dorsalis pedis artery can be prepared as an *in situ*, reversed, or nonreversed vein graft, without any significant difference in outcome.¹¹³ With the *in situ* or nonreversed graft, the valves may be lysed blindly or, preferably, cut under direct vision with an angioscope. This also

FIGURE 50-7. Temporal photographs illustrating the methodical use of the dorsalis pedis bypass for limb salvage. Evaluation for ischemia in a patient with gangrene (**top photo**) revealed extensive lower extremity arterial occlusive disease and a patent dorsalis pedis artery. A bypass to the dorsalis pedis was performed (**middle photo**). Once the foot was fully revascularized, a local amputation was performed, with resultant adequate healing and limb salvage (**bottom photo**).

allows for concomitant angioscopic assessment of the vein to detect any intraluminal abnormalities.¹¹⁴

Active infection in the foot is commonly encountered in the complicated ischemic diabetic foot. However, it is not a contraindication to dorsalis pedis bypass, as long as the infectious process is controlled and located remotely from the proposed incision. Adequate control implies resolution of cellulitis, lymphangitis, and

FIGURE 50-8. Vein graft patency, limb salvage, and survival rates for nearly 1000 patients at the authors' institution, all followed for 5 years or more. Note the virtually identical rates for patients with and without diabetes (DM and NON-DM). (Reproduced from Akbari et al.¹¹⁷)

edema, especially in areas of proposed incisions required to expose the distal artery or saphenous vein. The results of 56 vein bypasses to the dorsal pedal artery in patients with ischemic foot lesions complicated by infection were recently reviewed.¹¹⁵ This included 15 patients with severe gangrene, osteomyelitis, and/or deep space abscess. The average duration between admission and bypass was 10 days. Although there was a 12% wound infection rate, the primary graft patency was 92% at 36-month follow-up. This aggressive approach to revascularization in the ischemic and infected foot resulted in a limb salvage rate of 98% at the end of 3 years.

In the patient with an ischemic heel ulcer or gangrene, first consideration should be given to the posterior tibial or plantar arteries if they are patent by preoperative imaging. However, the absence of a patent posterior tibial artery is not a contraindication to arterial bypass and limb salvage. The role and efficacy of dorsalis pedis artery bypass in the treatment of ischemic heel lesions was recently examined in 96 patients who had undergone pedal bypass for heel ulceration.¹¹⁶ Compared with a similar cohort of 336 patients with forefoot lesions undergoing dorsalis pedis bypass, there were no differences at 5 years with respect to primary patency, secondary patency, or limb salvage. More importantly, dorsalis pedis bypass accomplished complete healing in 87% (84/96) of heel lesions, with healing rates being independent of the presence or absence of an intact pedal arch, and it allowed for a limb salvage rate of almost 90% at 5 years.

Despite the technical success of lower extremity bypass in patients with diabetes, concerns continue about long-term patient function and survival. To evaluate the question of late graft patency, limb salvage, and survival among diabetic patients, a recent report reviewed the experience with lower extremity revascularization in a largely diabetic population of nearly 1000 patients followed for 5 years or longer.¹¹⁷ A total of 962 vein grafts were performed on 843 patients, of which 83% (795 grafts) were in patients with diabetes. Minimum follow-up was 5 years and extended up to 9 years. The dorsalis pedis or plantar/tarsal arteries served as the outflow artery in 271 (35%) of the diabetic patients. Cumulative 5-year primary graft patency was 74.7% overall, with no difference among patients with and without diabetes (diabetic 75.6% versus nondiabetic 71.9%). The secondary graft patency rate was 76.2% for the entire cohort and was also similar between the diabetic and nondiabetic group (diabetic 77% versus nondiabetic 73.6%). Most importantly, 5-year limb salvage and survival rates were virtually identical in diabetic and nondiabetic patients. The overall limb salvage rate was 87.1% (diabetic 87.3% versus nondiabetic 85.4%).

Survival at 5 years was 58.1% in the entire cohort (diabetic 58.2% versus nondiabetic 58.0%). These data strongly emphasize that concern for long-term mortality, limb loss, and graft patency in diabetic patients is unnecessary and should not prevent the aggressive attempts at distal bypass required for limb salvage (Fig. 50-8).

Following successful revascularization, secondary procedures may be performed for both limb and foot salvage. Chronic ulcerations may be treated by ulcer excision, arthroplasty, or hemiphalangectomy. In the patient with extensive tissue loss, both local flaps and free flaps may be used. Due to the architecture of the diabetic foot, underlying bony structural abnormalities are often the cause of ulceration and may be corrected by metatarsal head resection or osteotomy. Heel ulcers may be treated by partial calcaneotomy and local (e.g., flexor tendon) or even free flap coverage.

CONCLUSIONS

The patient with diabetes and peripheral vascular disease represents a uniquely complex pathophysiology involving microcirculatory and macrovascular disease. Because much of the disability

FIGURE 50-9. Beginning with the introduction of the pedal bypass in 1984, and concomitant with a rise in all distal lower extremity arterial reconstructions, there has been a significant drop in every category of amputations at the authors' institution. TMA, transmetatarsal amputation; BKA, below-knee amputation; AKA, above-knee amputation. (Reproduced from LoGerfo et al.¹⁰⁸)

and morbidity of diabetes are directly caused by these vascular changes, an understanding of diabetic vascular disease is critical for reducing the overall morbidity and mortality of diabetes.

Knowledge of diabetic vascular disease should be incorporated into every aspect of the treatment plan. Taking a systematic and aggressive approach to diabetic foot disease has resulted in improved limb and foot salvage. As can be seen in Fig. 50-9, there has been a significant reduction in every category of lower limb amputation since 1984, with a concomitant increase in the number of patients undergoing arterial reconstruction and a greater application of the dorsalis pedis bypass graft. It is very likely, therefore, that further awareness of diabetic peripheral vascular disease can lead to a greater reduction in overall diabetic morbidity and mortality.

The Diabetic Foot

William C. Coleman

INTRODUCTION

The history of caring for the feet of persons with diabetes is fraught with frustration for medical professionals, family members, and patients. During the last decade of the twentieth century there has been a continuing refinement of interventional techniques to improve vascular flow to the lower extremities of persons with diabetes. New topical medications and dressings have been introduced to improve the management of foot wounds in diabetic patients. Despite these advances, during this same period of time, there has been a disappointing 22% increase in the total number of amputations performed on this diabetic population.

During the 1980s more than 55,000 diabetic foot amputations were performed annually in the United States.¹ In 1991, the U.S. Department of Health and Human Services set several goals it wanted to achieve by the year 2000. One of these goals was to lower the annual number of amputations of the feet of diabetics by 40%.² By the end of the 1990s the annual number of lower extremity amputations in the diabetic population had risen to over 67,000.³

In the United States, the majority of these amputations have been done on patients who receive Medicare benefits. Wrobel and colleagues found that diabetes-related amputations were 53% of all amputations within the Medicare population in 1996 and 1997.⁴ There were 44,599 major amputations in the Medicare diabetic population, or 3.69 amputations per 1000 patients with diabetes, versus 0.39 amputations per 1000 patients among the nondiabetic patients. The highest rates of amputation among persons with diabetes on Medicare were in California, Texas, New Mexico, and the upper Midwest and mid-Atlantic states.

The answers to reducing the majority of these amputations have been emerging over the past 20 years. Successful amputation prevention practices have been repeatedly confirmed by several studies over the past two decades. At Grady Memorial Hospital from 1972–1974, the amputation rate dropped 50%.⁵ The amputation rate declined 44% at Kings College Hospital in London in 2 years.⁶ In Memphis, a 68% reduction was achieved in 2 years.⁷ Assal applied his principles to the clinical practices of the University Hospital of Geneva, and the rate of below-the-knee amputations dropped 85% in 4 years.⁸ The first randomized, blinded, prospective controlled trial was reported by Litzelman and colleagues.⁹ Their experimental group was 0.41 as likely to develop serious foot lesions as the control group.

In Spain, 318 diabetic patients with neuropathy were followed by Calle-Pascual and associates for 3–6 years for their compliance

with participation in an education and foot monitoring program. The program entailed an extensive educational program, changing from inadequate to more adequate foot care behavior within the first 6 months, regular visits to a routine foot care specialist, at least one foot review every 6 months, and an annual diabetic treatment review. One group (223 patients) complied with all aspects of the continuing program and a second group (95 patients) did not. Seven ulcers developed on six patients in the first group and 30 ulcers appeared on 26 patients of the second group. The second group had 19 lower extremity amputations (LEAs) and the first group had one LEA. The compliant group had a 13 times lower risk of experiencing a first foot ulcer than the less compliant group.

Often, when clinicians hear of the results of these studies they will develop seminar programs for professionals and patients in their communities. Unfortunately, even with the best intentioned small educational seminars, focus groups of physicians and nurses, and programs that do not target specific professional behavioral changes have failed to improve the morbidity statistics for diabetic foot pathology.¹¹ As in the case of the goals set by the Department of Health and Human Services in the United States around the world national programs were developed to decrease amputation rates among diabetic populations throughout the last decade of the twentieth century. All of these large-scale, national initiatives failed to demonstrably decrease national amputation rates.

There are several examples of small-scale, single-institution success. Each of these came as the result of multidisciplinary foot care teams directed by a knowledgeable, influential leader. In all of these studies foot specialists, and/or specialized education techniques on foot care, were incorporated into multidisciplinary programs. In all of them, regular preventive visits were scheduled to help the patients monitor their feet and to reinforce the need for constant protective behavior.

As cited above, the program that has produced the most effective reduction of amputations published to date (85%) was headed by Assal at the University of Geneva. Assal contends that this problem persists because medical education poorly prepares the professional for the management of chronic diseases. The professional education is focused on the diagnosis of the disease followed by the treatment. But the educational process does not prepare the physician for the psychological and sociological problems that emerge when patients have to be constantly active in the management of a lifelong disease. In these chronic diseases a more holistic approach is warranted.¹²

Vasculopathy and Neuropathy

When a medical professional thinks of the spectrum of diabetic foot problems, two major contributing factors come to mind. These are peripheral neuropathy and peripheral vascular disease. In the context of foot management, it is the neuropathy that increases the likelihood that the person will develop a serious foot wound. Peripheral vascular disease rarely increases the chance of injury occurring, but an injury to a limb with severe arterial occlusive disease increases the possibility of limb loss.¹³ A moderate vascular impairment may be present without symptoms and may be compatible with the natural life expectancy for the limb. More severe disease may be capable of maintaining the tissues as long as no significant injury occurs. If an ingrown toenail or ulcer then occurs, and remains untreated because of a lack of pain sensation, the infection may spread throughout the foot, creating a gross infection that demands more blood supply than the impaired vessels can provide. The resulting gangrene may demand an amputation. The hospital records may show the cause as diabetic gangrene or vascular insufficiency, and may thus fail to correctly identify the neuropathy that allowed the process to continue undetected by the patient, until it was too late to salvage the limb.

At the center of the success of the programs that are able to achieve significant reductions in their numbers of lower extremity amputations is their ability to manage the ramifications of lower extremity sensory loss.

INJURY PREVENTION

During a meeting of the National Diabetes Advisory Board in 1980, a group of experts was asked to make recommendations that would result in better foot care and prevention of amputation. Those who expected advice on modern medications or vascular surgery were surprised when the first recommendation was for a national campaign to advise doctors to take off the patient's shoes.¹⁴ It was determined that the primary problem was that patients did not complain to their doctors or report the early stages of their foot disability because they had no pain. Therefore, doctors must take the initiative and look for early lesions. Physicians are 3–4 times more likely to examine a patient's feet if the shoes and socks are removed before the doctor enters the examination room.¹⁵

This aspect is mentioned first because many physicians overlook this simple maneuver. It may seem incredible that a person would walk on a foot and fail to note that it was swollen and infected or that it had an open ulcer on the sole. However, when sensation is lost, individuals commonly lose a sense of identity with their insensitive parts, and thus fail to note obvious problems. An insensitive limb feels like a wooden block fastened to the body and is treated as such. In a sense, such action may be a deep rejection of a "dead" body part.

As the result of following 51 of their regular diabetic foot clinic patients, Mantey and associates found that foot ulcers most frequently recurred in patients with the poorest glycemic control and the most profound distal neuropathy.¹⁶ They also found that those with recurrent ulceration tended to delay reporting early signs and symptoms of the new injury.

Every health professional who wants to help these people needs to know this and to help the person understand the consequences of this neglect. If the patients recognize the danger, they will be able to readjust their mindsets to compensate for this lack

of feeling. They can be helped to give very special conscious care to make up for the potential for subconscious neglect. Only with understanding and education will they obey rules of foot care which otherwise might be regarded as unnecessary and unimportant. One session is not enough. Patients need to have their foot consciousness reinforced frequently and in diverse ways, especially if they are thought to have slipped into neglect. Such education and reinforcement must be done with sympathy, understanding, and good humor if it is to succeed. The patient is quick to detect an impatient, angry, or intolerant attitude from the health care professional, and this will only lower the patient's self-image, and may lead to concealment of the problem foot next at the next medical checkup.

Soon after a person has been told that they have diabetes and become aware that it will be with them for the rest of their life, they go through stages of acceptance similar to the psychological adjustment we experience after the death of a close acquaintance.¹² These may include denial, revolt, bargaining, depression, and/or acceptance. The rate at which an individual passes through these stages varies. When the patient is diagnosed with subsequent peripheral neuropathy and learns of the lifestyle changes necessary to successfully protect the feet, in most cases a second period of psychological adjustment is needed. To compound the problem of foot care, very few persons with diabetes lose all of the feeling in their feet. The medical team and family members are faced with the task of effectively achieving compliance with needed lifestyle changes to protect the feet while patients still have some sensation in their feet. Physicians must be aware that these psychological and physical factors can be present and may interfere with successful foot care management.

PROTECTIVE SENSATION

The threshold of sensation that protects a normal foot strikes a very delicate balance. The purpose of pain sensation is not to cause pain, but to allow the body to act to minimize damage. A person who has lost some pain sensation has not lost the ability to feel pain; he or she feels it at a higher level of stress. It takes more pressure, higher temperatures, and more prolonged ischemia before the residual peripheral nerves are activated.

Peripheral, symmetrical, lower extremity sensorimotor polyneuropathy affects approximately 50% of all persons who have had diabetes more than 15 years.¹⁷ It does not take total sensory loss for trophic ulcers to develop in persons with diabetes. Gross testing for pinprick or for touch may reveal remnants of sensation. Therefore, one should not be surprised if breakdown occurs. The problem is that a foot may be vulnerable to damage long before gross sensory loss is noted. The physician or therapist must identify the degree of sensory loss that puts a person at risk. This involves a quantitative test of sensation, which should be repeated at least annually for every person with diabetes. Because sensory mapping is time consuming, we have tried to identify the simplest and fastest test that will discern feet that need protection and that will identify the areas of the foot that are most at risk.

The sensory test used in many specialist clinics is based on the principle of von Frey.¹⁸ He used horse hair of various thicknesses and lengths, and noted that the force needed to bend a given hair was the same every time. This principle could be used to quantify sensibility. Semmes and Weinstein¹⁹ used the same principle with a series of monofilament nylon fibers of varied diameters. These

were calibrated to bend when different forces were applied to the ends of the fibers.

In 1986, Birke and Sims published a study of insensitive feet, using selected fibers from the Semmes-Weinstein series.²⁰ They demonstrated that patients who could feel the filament that bent under a 10-g force (designated 5.07 on the Semmes-Weinstein scale) were unlikely to suffer damage and ulceration to their feet under normal walking conditions. Patients who could not feel that fiber were the ones who had problems. This was a retrospective study, but the 10-g fiber has since been used prospectively to identify patients who need special care and education, as well as special care in choice of shoes. They have found it to be a reliable index of vulnerability. This group now recommends the use of just three fibers for the testing of diabetic feet. These are: (1) the 1-g fiber (Semmes-Weinstein rating of 4.17), which can be felt by normal feet and which identifies the early onset of sensory neuropathy at a stage when special care may not be necessary; (2) the 10-g (5.07 rating) fiber, to identify the areas that need to be protected; and (3) a third fiber (75g), to identify areas that have lost all protective sensation (6.10 rating). Clearly, the 10-g fiber is the important one. Busy diabetic clinics may benefit from frequent tests with one fiber, rather than less frequent full mapping of sensation.

RISK CATEGORIZATION

With the use of a quantifiable test for protective sensation, the clinician can then begin to identify patients most likely to develop neuropathic injury. Several studies have been conducted during the last decade to identify factors that add to the morbidity of the diabetic foot.

In a prospective study of 749 patients, Boyko and coworkers found diabetic foot ulcers develop as the result of multiple factors.²¹ These factors included neuropathy, diminished vascular perfusion, foot deformity, higher pressures under the foot, severity of diabetes, and comorbid complications from diabetes. In a study of 225 subjects, Lavery and associates²² found that persons with diabetes and neuropathy were 1.7 times more likely to develop foot ulceration. If the person also has foot deformity (limited great toe motion, bunion, or toe deformity), the patient is 12.1 times more likely to experience a foot ulcer. If they have an amputation of the lower extremity, their risk of ulceration on the opposite limb increases to 36.4 times normal.

By being aware of these data, the clinician can begin to categorize patients according to their risk of developing foot injury.

Category 0

This category includes all persons diagnosed as having diabetes. These patients need to be monitored periodically for glycemic control and the development of pathology related to their diabetes. These people also need to be made aware of the relationship between glycemic control and the emergence of comorbid consequences. They need to be educated about the signs detailed in previous chapters that indicate that damage to the vasculature or nerves is occurring. This is a good time to begin counseling the person on the need for properly fitting, conservative footwear. These patients should be evaluated each year for signs of lower extremity neuropathy or arterial occlusive disease.

Category 1

A person is placed in this category when they have been identified as having peripheral neuropathy, either by failing to feel the Semmes-Weinstein 10-g monofilament, or because of excessively dry skin. Dryness of the skin is a good indicator of autonomic nerve loss. The authors have found that feet that can sweat normally rarely become ulcerated. This does not mean that it is the loss of the autonomic fibers that makes the foot vulnerable. It suggests that a significant loss of touch sensation occurs at about the same time as the loss of sweating.

These persons are at much higher risk of pedal injury. They need to be educated on the need for daily visual foot inspection. They must be made aware that they can no longer trust the feelings in their feet as an indication of the presence or severity of a wound. They must contact their physician or other medical staff member as soon as possible for assistance with the care of the wound. Their prior experience has not prepared them for managing wounds in the presence of neuropathy.

If at all possible, persons in this category must have a competent professional ensure that all of their shoes fit properly. Tapered-toe shoes, pumps, and other footwear that excessively stress the toes pose a risk to the foot. Toenails and calluses should be maintained by a trained medical professional. These patients should have their feet medically evaluated at least every 6 months.

Category 2

Persons in this category not only have diabetes and neuropathy, but they also have a foot deformity. The deformity may be very subtle, such as a limited subtalar joint range of motion, or very obvious, as in the case of a large bunion deformity. The lesser toes commonly curl into clawed-toe deformity on diabetic patients with neuropathy. Any bony prominence, significant lack of joint motion, or gross malalignment of the foot qualifies as deformity.

The presence of elevated blood glucose results in the glycosylation of many tissues in the body. Zilberberg found a higher density of nonenzymatic, cross-linked pentosidine in the plantar skin of amputated diabetic feet as compared to similar skin from nondiabetic controls.²³ The skin of the feet of persons with diabetes was less flexible. Nonenzymatic glycosylation has been found to affect ligaments, resulting in restricted motion of several joints. This was first noted in the hands, but later was also demonstrated in the subtalar, ankle, and first metatarsal-phalangeal joint. Birke and coworkers found a correlation between first metatarsal-phalangeal motion and a history of ulcers of the first metatarsal head.²⁴ When a person has limited subtalar range of motion along with neuropathy, significantly higher plantar pressures are found.²⁵

Surgical correction of the deformity may be indicated. The presence of neuropathy obviates symptoms as an indication or contraindication for surgery.

Strict adherence to the use of proper footwear at all times is essential for patients in this category. Often, custom footwear or shoe inserts are needed to lower the risk of injury. These patients should see a foot specialist every 3 months for nail and callus care. This professional must examine the foot for changes in shape or mobility, review the patient's footwear, and emphasize the need to report any findings from the patient's self-foot examinations, as well as the need to treat any lesion found as soon as possible.

Category 3

Neuropathic feet most likely to ulcerate have been ulcerated before or have had significant morphologic changes to the foot as the result of Charcot's arthropathy. This places these patients at the highest risk of developing a neuropathic foot wound. Everyone in this category must wear prescription footwear to lower weight-bearing stress at the previous site of ulcer or Charcot's deformity. This footwear must be worn at all times. The clinician must ensure that the patient is aware that barefoot walking, as well as walking in stocking feet, slippers, and nonprescribed footwear, poses a threat to the foot. Every step must be protected. Even the nightly walks for nocturia must be protected by footwear.

These persons should visit the foot clinic every 2 months, and in extreme cases every month. In addition to all of the treatments mentioned in the previous categories, their footwear needs to be examined at every visit for proper fit and function.

IMPACT OF AUTONOMIC NEUROPATHY

Autonomic neuropathy can result in anhidrosis of the pedal skin. In the normal foot, the superficial layer of the skin is kept constantly hydrated by sweat. In the hydrated condition, the keratin of the skin is soft and pliable. If a flake of thickened callus is shaved off a foot and moistened, it can be rolled up like a piece of rubber, or it can be stretched and will spring back to shape. If the same flake of keratinized skin is then allowed to dry in the sun, it becomes hard and brittle and loses all ability to stretch. The same change occurs in the keratin layer *in situ* on the foot in the absence of sweating. When such skin is subject to flexion and extension as occurs at the joint creases of the toes and at the curve of the edge of the sole, the keratin cracks. Early in their development such cracks are limited to the stratum corneum layer of the epidermis, but they do allow a superficial inflammation to develop. This can eventually result in a chronic dermatitis in the lower third of the leg (Fig. 51-1). In the sole, the cracks become inflamed and stimulate build-up of more callus along both margins of the crack. The thickened plates of hard callus allow no flexion or stretch, and thus concentrate and localize all movement to the keratin-free cracks. This makes the condition worsen, until deeper layers of the epidermis become inflamed or even torn open where the crack makes them vulnerable. The final result is often an open ulcer and deep infection.

If keratin cracks have already occurred, they are treated by: (1) paring down the callused edges of keratin buildup, (2) painting the crack with gentian violet to dry the base, and (3) providing some measure of splinting to minimize the movement of the keratin plates. This may be done by splinting an affected toe by making the shoe sole rigid, or by wearing a molded insole that turns up around the edge of the sole or heel. It is also helpful to use an insole that has been molded to the foot. It should offer support up around the edges of the sole and heel where cracks commonly occur (so called "pinch calluses"). These are found wherever the skin is pinched in the unsupported angle between the supported sole and the side-wall of the shoe.

CALLUSES

When subjected to repeated pressure, skin thickens to form callus tissue. Callus strengthens the skin's ability to withstand pressure. Callus is protective if it remains a moderate thickness, as on the

FIGURE 51-1. Dry keratin is not pliable and tends to crack at skin flexion sites. The superficial inflammation that follows can lead to chronic dermatitis or to ulceration.

hands of construction workers. If the callus becomes too thick, it can act as a foreign body. At that point, when pressure is again applied to the area, the callus can contribute to damage in deeper tissues. In a sensate individual, this results in pain, and the person alters their behavior to find ways to relieve the pain, as with the woman who searches for adhesive pads to relieve her toe corns rather than change to more comfortable footwear. In one study of insensate feet on diabetic patients, plantar callus was highly predictive of eventual foot ulceration.²⁶ These calluses can also add to the increase in stress on the foot. The removal of callus tissue has been shown to reduce these pressures by 29%.²⁷

WOUNDS OF THE FOOT

By the time the clinician first examines an ulcerated foot, the initial cause of the problem may be lost from the patient's memory, and it may be hard to diagnose from the appearance of the ulcer. Thus all ulcers are often lumped together under generic terms such as pressure ulcer or diabetic ulcer. Prevention and correction of damage to the insensitive foot requires that the physician and patient understand the actual pathology of the early stages of damage to the foot, and the actual forces that may cause the damage. The focus should be directed toward the external mechanical factors that cause the foot to break down. The insensitive diabetic foot is not really very

much weaker than a normal foot; it is just less well protected because of decreased pain sensation.

A foot may be damaged by external forces in one or more of three ways: (1) An unrelenting, low pressure, as from a tight shoe, may cause ischemic necrosis or a pressure sore. Its pathology is similar to that of a decubitus ulcer. (2) A much higher pressure may cause direct mechanical damage, as when a foot lands heavily on a sharp stone, broken glass, or a thumbtack, and the skin is broken or penetrated. (3) Constantly repeated moderate pressure with every step may result in inflammation at high-pressure points, followed by blister or ulcer formation. This is not ischemic necrosis, because the blood supply is not continuously blocked, but is more of an inflammatory enzymatic autolysis. We have termed these three pathogenic factors *ischemia*, *mechanical disruption*, and *inflammatory autolysis*.

Ischemic Pressure Ulceration

Decubitus ulcers develop when a section of otherwise healthy skin is subjected to unrelenting pressure. The skin over the sacrum or over the backs of the heels is a common location for this type of wound. A neuropathic foot is also vulnerable to this form of injury. Sustained external pressure that is greater than capillary or local arteriolar blood pressure will occlude these vessels wherever the tissues are compressed between the shoe and an underlying bony structure.

A good deal of experimental work has been done by Brannemark,²⁸ Daly,²⁹ and Romanus³⁰ to determine exactly how much external pressure it takes to block the blood flow in peripheral capillaries and produce a state of ischemia. Kosiak and others have studied the relationships between the level of external pressure and the time it takes to produce necrosis or ulceration.³¹ Kosiak's diagram (Fig. 51-2) shows that at higher pressures gangrene occurs sooner than at lower pressures.

These studies are not discussed in detail because it has proven impractical to measure these small pressures on the foot in a clinical

setting. Also, the structure of the sole of the foot offers mechanical protection to its blood vessels that makes it impossible to standardize thresholds of safety for different parts of the foot. However, some important generalizations about protecting the foot from this type of damage will be discussed.

Localized necrosis of the skin of the foot may occur with pressures as low as 1 pound per square inch (psi). Each member of the diabetic clinical team should demonstrate to himself or herself, and to every patient, how little pressure it takes to produce ischemia. This can be done by pressing a glass slide onto a fingertip or toe until the skin is seen to blanch. This is ischemia. It should be obvious that tight shoes often exceed such a pressure. It is also obvious that such ischemia is painless. Only after an hour or more will pain force normal people to take off their shoes. A person with diabetic neuropathy will keep them on indefinitely.

At pressures of 1–5 psi, such as might be found in a tight shoe (non-weight-bearing), it takes many hours to produce actual necrosis. Although it is not practical to measure pressures inside every shoe, it is very practical to measure time, and it is not difficult to observe the reaction to pressure, such as redness and hyperemia after removal of a shoe. A new shoe should be worn for only 2–4 hours on the first day. When it is removed, the patient should look carefully for an area of redness and feel for a patch of warmth. If the skin becomes flushed after only 2 hours, it is good evidence that it might become severely damaged if that shoe were worn for 8–10 hours. A leather shoe may be moistened (using a 50% water/50% isopropyl alcohol solution) and stretched on a special last, and may then be worn again for short periods until it is broken in. People with diabetes should be advised to wear only leather shoes, because vinyl and other plastic uppers do not adapt to the shape of the foot to relieve localized pressure.

An excellent habit for a diabetic is the 5-hour shoe change. This involves keeping one pair of shoes at the office or factory. The patient wears one pair of shoes to go to work and at work until lunch time. At lunch, the patient changes shoes and leaves his or her morning shoes in the locker. The second pair is worn until the patient gets home in the evening, when he or she changes into house shoes or slippers, which are worn until bedtime.

Thus each pair of shoes is worn about 5 hours (i.e., 7 AM to noon, noon to 5 PM, and 5 PM to 10 PM). If this habit is developed the patient will never be in danger of an ischemic pressure ulcer. Even if one pair of shoes is tight, it will not cause necrosis in 4 hours, and the next pair will either not be tight, or may be tight in a different place.

An insensitive foot may develop a pressure ulcer in a previously well-fitting shoe because an insole, pad, or dressing has been added inside the shoe (Fig. 51-3). Bulky dressings of any sort should not be applied to an insensate foot if that person is going to walk. If a foot needs dressing, the patient should probably be in bed or in a cast. If a foot must be in a shoe, it should be a special protective shoe. If a foot needs more than a 1/8-inch-thick additional insole, an extra-depth shoe should be used (Fig. 51-4).

It is very uncommon for ischemia to cause problems on the sole of the foot. This is because a person with diabetes is generally active; thus pressures from weight bearing are intermittent. The only constant pressure on the foot of an active person is due to circumferential tension from a shoe, strap, or bandage; thus the primary force is tension. Pressure occurs at right angles to the tension (an open shoe may be loose, but when the laces are pulled tight, the foot feels pressure). The simple mechanical rule that links pressure and tension states that tension results in pressure only when the line of tension passes around a curve. The pressure

FIGURE 51-2. Kosiak's classic experiment showing how there is an inverse relationship between the pressure and the time it takes to cause ischemic necrosis. Pressure-time relationship noted in 62 separate experiments on 16 dogs: X, ulceration; •, no ulceration. (Reprinted with permission from Kosiak.³¹)

FIGURE 51-3. If a bulky dressing or a thick insole is added and the foot forced back into a previously well-fitting shoe, the increased pressure may result in local gangrene.

that results from tension is inversely proportional to the radius of the curve:

$$\text{Pressure} \sim \frac{\text{Tension}}{\text{Radius}}$$

In the diagram of the transverse section of a forefoot in a shoe (Fig. 51-5), three curves are drawn: (1) the curve of the dorsum of the foot is part of a large circle with a large radius; (2) the curve around the first metatarsal head has a small radius; and (3) the curve of the lateral border of the foot is the smallest and has the smallest radius.

Since the tension in a tight shoe is equal all around the foot, the pressure due to the tension will be least on the dorsum, high on the medial border, and highest on the lateral border (Fig. 51-6). The sole is more or less straight and therefore suffers negligible pressure from tension. The medial border may be curved in two planes

FIGURE 51-4. An extra-deep shoe provides more vertical space for the toes and metatarsal head area. Such shoes are required when insoles exceed 1/8 inch in thickness.

if there is a bunion or hallux valgus, and may thus have a higher pressure than the lateral border. If a patient has a bunion, it is an extra hazard, and surgical correction should be considered if only to prevent future ischemic ulceration.

Although it may seem logical to encourage persons with diabetes to purchase loose shoes, this should be avoided. The danger from friction is as great or greater than that from ischemia. Friction blisters or ulcers may occur behind the heel or around the rim of the shoe because the foot moves up and down due to the loose fit. These blisters and ulcers are prevented by ensuring that the heel is snug and well shaped, and that the lacing or strap over the dorsum reaches far enough up and back over the instep to hold the shoe firmly on the foot.

In summary, to prevent ischemic ulcers, shoes should have leather uppers and be carefully fitted. Feel the medial and lateral borders of the forefoot. New shoes should be worn only 2 hours on the first day, and then the foot should be carefully inspected for areas of redness or heat. Time is an essential element with this form of damage. It takes a long time for low pressure to result in

FIGURE 51-5. Cross section of a forefoot showing that the dorsum is part of a large curve radius (R_1), the medial border is part of a smaller curve radius (R_2), and the lateral border has the smallest curve radius (R_3). The pressures from a single circumferential band of equal tension all around will be slight on the dorsum (P_1), greater on the medial side (P_2), and greatest on the lateral border (P_3). When the tension is equal, $R_1P_1 = R_2P_2 = R_3P_3$.

FIGURE 51-6. Pressure necrosis at the lateral border of an insensitive foot due to the wearing of a tight shoe all day.

ischemic damage. Periodic removal of shoes during the day eliminates this risk. The patient should be advised to change shoes every 5 hours. Routine changing of shoes at noon and 5 PM or other regular intervals can aid the patient to develop an easily remembered routine.

Direct Mechanical Damage

Yamada,³² in his book on strength of biological materials, quotes Yamaguchi³³ as saying that the skin of the human foot has a tensile breaking load of 2.5 kg/mm and an ultimate tensile strength of 0.95 kg/mm². This means that sole skin may be torn by about 100 kg/cm² or 1300 psi. Thus it takes about 1000 times more force per unit area to damage skin directly than it does to damage it by ischemia (Fig. 51-7). Direct damage to the sole of the foot might occur if the whole weight of a 144-lb person were to rest on an area of $\frac{1}{9}$ of a square inch (Fig. 51-8). A woman wearing stiletto heels could penetrate the skin of a companion's bare foot if she stood on it with just one heel. Actual damage occurs at lower levels of pressure or tension if an element of shear stress is present.

FIGURE 51-7. His weight remains the same, but the area of the stump on which he stands is smaller. Under the foot, damage is caused more readily by narrowing the area of support than by increasing force.

FIGURE 51-8. Barefoot walking is good for the feet, but only if they are sensitive enough to respond to pressure.

In short, it is unlikely that a person wearing shoes could ever suffer direct damage from any external force unless a small, sharp object were under the foot inside the shoe. However, persons should be extra vigilant when walking around a construction site or a recently roofed building. The risk of stepping on a nail or screw capable of penetrating the shoe sole is much greater in these locations. Insensitive feet are sometimes damaged by walking in stocking feet or barefoot on broken glass, thumbtacks, or sharp stones. Such damage may be avoided completely by a simple rule that all diabetics should follow: "Never walk barefoot, always wear shoes with soles thick enough to prevent a thumbtack from penetrating to the foot, and always shake out your shoes before you put them on." Barefoot walking is very beneficial at all ages, but only when the feet are sensitive to pain.

Along with direct damage from very high forces, direct damage from heat, cold, or corrosive chemicals should be mentioned. All persons with insensitivity need to be alert to such danger and to maintain a margin of safety. They need extra socks when skiing, protective footwear in chemical plants, and special awareness of hot floors in automobiles and trucks. They should be wary of fires or car heaters, and they must never use steam pipes or electric heaters to warm their feet on a cold day.

Moderate Repetitive Stress

Inflammatory autolysis is by far the most common cause of ulceration in the diabetic foot. The pressures that cause it range from 20–70 psi, and are quite similar to the pressures that are ordinarily accepted by normal people who go jogging or walking briskly in firm-soled shoes. Such pressures do not do any harm to normal or diabetic feet unless:

1. They are repeated many thousands of times, day after day, on the same areas of the foot.
2. The tissues are already inflamed as a result of excessive mechanical stress.
3. The tissues are structurally abnormal as a result of previous ulceration and scarring.

The typical diabetic foot ulceration is postulated to begin as a callus on the surface of the skin. Due to repeated impacts to this callus as a result of walking, breakdown occurs between the callus and the deeper tissue.³⁴ This breakdown comes as the result of the accumulation of inflammatory cells.³⁵ These cells release lytic enzymes into the tissues. These enzymes lyse the tissues, resulting in

a pocket of accumulated fluid. Because the person is insensate, he or she continues to walk on the foot. The inflammation and associated dissolution of tissue becomes exacerbated by hydraulic fluid pressure as the result of stresses on the pocket. This eventually results in the formation of a blister adjacent to the callus or a break in the skin. The hole in the skin will be smaller than the deeper pocket. For the inexperienced clinician, this could result in an underestimation of the extent of damage. When a blister rather than an open wound is found, and the foot is neuropathic, the clinician should appreciate that the real damage is deep to the callus rather than under the blister.

Figure 51-9 shows the histology of rat footpads that were subjected to 10,000 repetitions per day of 20 psi for several days. The rats were lightly anesthetized and had one foot placed in a machine. A piston applied repeated intermittent stress to the footpad to simulate walking or running. The pressure and the number of repetitions per day could be varied. In this experiment the footpads looked normal, though a little swollen, for the first 3 days. They finally broke down and ulcerated about the seventh or eighth day. However, as early as the second or third day, the histology showed invasion of the area by many inflammatory cells. Small foci of necrosis developed in the areas that were crowded with inflammatory cells.

In the inflamed condition, the footpads were swollen and hot, and they had a changed elasticity and viscosity. Thus the same

external forces were now more damaging because they were less well absorbed and dissipated by the tissues. Also, the invading inflammatory cells are known to contain lysosomal enzymes. On further mechanical insult, these could have been spilled into the tissues to cause local foci of necrosis. The following conclusions can be derived from these studies:

1. The breakdown of the tissues was the end point of a long process of repeated moderate stress that seemed quite harmless in its early stages.
2. The final breakdown and ulceration could be predicted by the physical signs of local swelling and heat.
3. The breakdown and ulceration could be prevented by discontinuing the repeated stress as soon as the swelling and heat began to persist from one day to the next.
4. The breakdown could be prevented either by decreasing the amount of pressure per repetition (i.e., per step), or by keeping the pressure the same and reducing the number of repetitions.

The early stages of these experiments have been repeated using human fingertips without anesthesia. Repeated pressures of 20 psi were comfortable for several hundred cycles, but then the fingertips gradually became more and more painful until withdrawal became essential. At that stage the fingertip was red, somewhat swollen, and warmer. Within a few minutes it developed a temperature of 4°C higher than the other fingers. The discomfort passed within an hour or so. Upon returning the next day to repeat the experiment on a different finger, the subject could tolerate about the same number of repetitions. However, repeating the stress on the finger that had been exposed the previous day resulted in much more rapid onset of pain. The hyperemia and heat also developed sooner and lasted longer.

By studying the thermographic patterns of the sole of the foot of normal runners (Fig. 51-10), each individual can develop his or her own pattern of "hot spots" that appear on the sole after running a couple of miles. However, after further periods of running, the subject alters his or her gait just enough to spare the now-tender areas of the foot and put more stress on less involved parts of the foot. This constant change of stress patterns on the foot in response to the perception of tenderness and changing thresholds of pain is probably the most important factor that prevents breakdown and ulceration in normal individuals. The fact that persons with diabetes do not appear to limp or change their gait in the early stages of traumatic inflammation may allow them to continue until they develop necrosis, a blister, or ulceration.

Stokes and associates were the first to quantify the correlation between high-pressure points under the insensate foot and ulcer sites.³⁶ Boulton and coworkers discovered that pressures under insensate feet are usually higher than pressures under normally-sensate feet.³⁷ It was later found that persons who have limited mobility in major joints of the foot generate the highest pressures and should be considered to be at high risk of ulceration.²⁵

WALKING MANAGEMENT

Every person who has insensitive feet needs to be educated about the dangers of repetitive, moderate stress to the feet and the need for extra foot protection to compensate for the reduction in sensation. Preulcerative changes (i.e., blisters, petechiae, erythema, and increased skin temperature) can alert patients and clinicians at a

FIGURE 51-9. A. Full thickness of footpad of rat, on second day of program in which 20 psi of pressure was applied 10,000 times per day to the foot of the anesthetized rat. This program simulated the repetitive stress on a human foot jogging 7 miles per day. B. Same experiment—third day. Note increased thickness (edema), thickened epithelium, and some inflammation. C. Eighth day. Specimen too swollen to fit on slide. Enormous hyperplasia of epithelium. Skin has broken down and ulcerated. This program resulted in ulceration in all of the feet that were involved. D. Similar footpad from rat after 6 weeks of a program in which the same pressures were applied, but only 8000 times per day (similar to 5 miles of jogging) and only 5 days per week. Note hyperplasia of epithelium, but footpad is not grossly thickened or inflamed. This program resulted in strong, well-conditioned feet.

FIGURE 51-10. Thermograph of a normal pair of feet (A) immediately after running and (B) after a rest. The subject had a button taped to the underside of his foot under the fifth metatarsal head. Note that the area that was over the button remains hot while the rest of the foot cools down.

stage when the foot can be better protected to prevent further damage. Patients need to know that they will be able to walk further if they reduce localized high-pressure areas on the sole. A study by Edmonds and colleagues demonstrated the value of proper footwear in the prevention of recurrent ulceration in a population of diabetics.⁶ They found an 83% recurrence of ulceration in patients who reverted to wearing their regular shoes, while only 26% who wore only their prescribed footwear had recurrence. In a controversial study in Italy, Uccioli and associates selected a group of diabetic neuropathic patients and randomly assigned them to either wear their own footwear or footwear with custom-molded inserts in extra-depth shoes for a year.³⁸ Of those who wore nonprescription footwear, 58.3% developed foot ulcers within a year. Of those who were wearing the custom-molded inserts in extra-depth shoes, 27.7% experienced foot ulcers within the year.

The best way to reduce pressure is to spread the stress over the entire surface of the sole. This may be accomplished in one of three ways: by using a soft sole or insole, a molded insole, and/or a rigid-soled rocker shoe.

$$\text{Pressure} = \frac{\text{Force}}{\text{Area}}$$

In a foot, the force is the weight of the body that is transmitted through the foot to the ground. This force may vary a little in running and jumping, but usually approximates body weight. When a patient is standing still, both feet share the load so that the area under pressure is large, and the pressure itself is thus usually under

20 psi and is harmless. When one foot is off the ground, in the swing phase of the gait, the other foot takes all the force. The pressure is therefore equal to the body weight divided by the total area of foot in contact with the ground (or shoe). This ranges from 10 to 25 psi, and is usually harmless, even after many repetitions.

While the "swing" foot is moving forward in preparation for the next step, the weight of the body is moving forward over the weight-bearing foot, that now enters the propulsive phase. In this phase, the heel leaves the ground and the entire body weight rests on the forefoot and toes. At this point the pressure is at the peak experienced during the walking cycle. The heel and midfoot bear no weight, and there may be only a few square inches to carry the body weight. This is when pressures under the metatarsal heads of the toes may rise to 40, 50, or 60 psi. It is these levels of pressure that will result in inflammation and ulceration if they are repeated too frequently.

SHOE INSERTS

If a soft material is placed under the foot, this results in an increase in the area of contact over which the force of weight bearing is dispersed. Figure 51-11 shows a tracing taken from five pressure-sensing devices on the sole of a normal foot while the subject was walking freely for four paces. The devices were taped on the great toe, the first, third, and fifth metatarsal heads, and the center of the heel. The pressure from each device was recorded in kg/cm² (1 kg/cm² = 14.2 psi). The third tracing (from the top in Fig. 51-11) showed the

FIGURE 51-11. Pressure tracings of a normal foot on three different surfaces. Note how the use of resilient, compliant materials results in equalization of pressures.

highest pressures. This was derived from the third metatarsal head (i.e., the center of the ball of the foot). At each step, the pressure rises moderately when the foot comes down flat and then rises to a peak when the heel is lifted, prior to the final thrust at toe-off. This subject walked four steps barefoot. His foot came down on a polished concrete floor for the first step, then on a sheet of regular cowhide shoe leather, then on a sheet of $\frac{1}{2}$ -inch-thick microcellular rubber, and finally on the concrete floor again. Notice that the peak pressure on concrete was 5 kg/cm^2 , on leather was about 3 kg/cm^2 , and on microcellular rubber was only about 1.5 kg/cm^2 .

In diabetics, a soft insole might offer greater safety than a hard insole because peak pressures would be lower. However, there are limitations to the use of soft insoles in regular shoes. No soft insole can have a great effect on pressure unless it is thick enough for the foot to sink into, so that pressure can spread over a wider area. Regular shoes do not have sufficient room for thick insoles. Also, even if a shoe were deep enough for a $\frac{1}{2}$ -inch-thick insole, the foot would move up and down in the shoe as the insole was compressed and decompressed, leading to friction blisters where the foot rubs on the shoe. For this reason, we prescribe thick, soft insoles only for open sandals. Inside a regular shoe, thin, soft insoles may be used, such as a $\frac{1}{8}$ -inch-thick Spenco insole, which is made of microcellular rubber covered with stretch nylon. This does reduce local pressure and shear stress, but only to a limited extent. Instead, we usually use a molded insole, so that even when the foot has prominent bones or hollows, the pressure can be spread out.

Thicker soft materials are effective when they are part of the outer shoe sole. Soft-soled athletic footwear has been shown to significantly reduce pressures under the feet 25–30% as compared to leather-soled footwear.³⁹ The benefit is greatest when the individual has higher-than-normal pressures under the feet when walking.⁴⁰

Molded Insoles

The advantage of molded soles is that the foot does not have to sink down into the material in order to spread the stress. A properly molded sole will meet the foot at every point at which it bears weight. In the past, the danger of using a molded shoe for an insensitive foot was that the shape of the insole might not fit the shape of the sole, and the patient would not know that it was improperly fitted. This was a common cause of secondary problems. For example, an arch support might be too high, or a metatarsal bar might be too far forward, thus increasing the pressure it was intended to relieve.

In the last 30 years there has been a revolution in moldable insole materials. Since the introduction of Plastazote in the 1960s, a whole series of closed-cell polyethylene foams have become available. Many of these materials are heat molded at about 140°C and are poor conductors of heat, so it is possible to mold them directly on the foot without causing burns. This ensures that every insole is a perfect fit, whether made on the foot, or even better, on a plaster model of the foot. The original Plastazote insoles were good, but they were subject to rapid wear and would “bottom out” after a few months. Firmer grades of Plastazote and other materials, such as Aliplast, XPE, and Pelite, now allow a wide choice of texture and lasting quality. It is also possible to make composite insoles with layers of microcellular rubber or polyurethane to support the polyethylene foam and improve durability. In some cases, the innermost layer of the sole may be of leather, wet-molded on a plaster model and backed by cork and latex.

Whatever materials are used, molded insoles should be custom-molded for each individual foot. Prefabricated arch supports or other modular inserts should no longer be prescribed for insensitive feet. Fully-molded insoles take up room in a shoe, and in many cases extra-depth shoes, with an additional $\frac{1}{4}$ – $\frac{3}{8}$ inch of vertical room, must be used to accommodate them. These are now available from P.W. Minor, Miller Shoes, Alden Shoe Company, and most recently from SAS (San Antonio Shoes). These shoes look like regular oxford shoes, so patients do not look as though they are wearing orthopedic footwear.

ROCKER-SOLED SHOES

The forefoot suffers maximum vulnerability when (1) the other foot is off the ground, (2) the heel is off the ground, or (3) the weight-bearing part of the foot is bending (causing shear stress). Maximum relief of local pressure and shear stress is obtained by (1) prevention of bending of the foot by making the sole of the shoe rigid, and (2) prevention of localized pressure on the forefoot by keeping ground contact further back, near the center of the shoe.

These criteria are fulfilled by the rocker shoe (Fig. 51-12). Studies by Pollard and associates have shown that a significant reduction of shear stress can be accomplished with a properly constructed rocker-soled shoe.⁴¹ If this shoe is to be custom-made, a plaster model of the foot should be taken with the toes somewhat dorsiflexed, so that the toe of the shoe is turned upward a little. This allows the heel to lift without the toe taking weight while walking.

FIGURE 51-12. Construction detail of a custom-made rigid-sole rocker shoe that minimizes pressures in the vulnerable forefoot area.

A regular extra-depth shoe may be made into a rocker by: (1) tilting the toe up a little, (2) adding a steel shank (Fig. 51-13) along the sole to make it more rigid, (3) adding an undersole which is thickened into a rocker behind the metatarsal heads, and (4) adding a molded insole.

PRESSURE FOOTPRINTS

In spite of the great care used in fitting shoes, there will be some patients whose stress is still not relieved, and it may even be worsened by the shoe prescribed. Since the patient cannot feel what is wrong, an objective way to detect pressure problems before the patient leaves the clinic is needed. During the past decade, electronic pressure-sensing tools have become increasingly sophisticated, but their expense and the time needed to conduct these tests still precludes their use as a daily clinical tool. On the other hand, the Harris footprint mat is inexpensive, takes little time to use, and has served well in this regard. It is an inexpensive, practical method that gives a result that the patient and all members of the team can easily understand.

The mat is made of vulcanized rubber and consists of small ridges of three different heights (Fig. 51-14). It is inked with a roller using washable printer's ink and covered with unglazed paper. When a patient stands on it, the part of the sole of the foot that bears the most pressure will flatten the high ridges and will print from the high, medium, and low ridges. Those parts that take less pressure will print only the high and medium ridges, while the

lowest-pressure points print only from the high ridges. Thus there is an instant record of the pressure pattern that is permanent and can be kept for comparison to subsequent prints (Fig. 51-15). The mat can be used in three ways: the hard footprint, the soft footprint, and the in-the-shoe footprint. All are dynamic and must be taken while the person is walking at a normal pace. An area of floor is set aside for footprints. It may be narrow, but should be long enough for four or five steps.

A line is marked for the start of the walk. The technician demonstrates the technique. The patient takes a practice walk, barefoot or in thin socks. The technician notes exactly where the foot comes down on the second step. He places an inked mat covered with paper on that spot (Fig. 51-16). The patient repeats the walk, lands on the mat, and walks on for two more steps. The footprint is of no value if the patient stops as soon as the footprint is taken. The highest pressure is usually in the propulsive phase of gait, and this is lost if the patient slackens off once the foot is down.

A soft footprint is taken in exactly the same way, except that a sheet of soft insole material, such as Spenco, is placed under the mat. The soft footprint shows just how much pressure reduction in

FIGURE 51-15. The footprint from the Harris mat shows high-pressure areas. The footprint is a valuable patient record.

FOOTPRINT TEST...

FIGURE 51-16. Premarked footprints may be used to help the patient place feet on the pressure mat. The cushion shown under the Harris mat is used in the soft-footprint test.

high-pressure areas can be expected from a soft insole, as shown in Fig. 51-17.

A number of precut insoles of the thinnest variety of Harris mat can be used to localize pressure points within the patient's shoe. Two or three different sizes can be cut from a single mat. They are kept and used over and over again indefinitely. An appropriately sized Harris mat insole is inked and covered with paper, which is held in position with small adhesive strips (Figs. 51-18, 51-19, and 51-20). It may be placed in the shoe or on the foot with the sock put on over it. In either case, the shoe is opened widely to allow the foot to step in without smudging the print. The shoes are laced and the patient told to walk briskly and normally for three or four steps. The shoe is opened carefully and the print removed.

This in-the-shoe print is usually creased and smudged; nevertheless, it is extremely valuable. It identifies the real continuing pressures that the patient will experience in the days ahead. Sometimes it is the only device that will convince the patient that their

FIGURE 51-17. Comparison of results of hard and soft footprints will demonstrate pressure relief from insole material.

FIGURE 51-18. The thinnest variety of Harris mat is cut into insole-shaped pieces and used to test shoes.

favorite high-heeled shoe is really dangerous. It may also demonstrate that a simple inexpensive shoe with an insole is really quite appropriate, and expensive special shoes are not needed.

By provision of special shoes, or by minor modification of regular shoes, the patient may spread the pressures of walking as widely as possible (Fig. 51-21). The amount of daily walking must also be limited so that damage can be avoided.

FIGURE 51-19. An example of an unacceptable in-the-shoe footprint when a simple insole was used.

FIGURE 51-20. A second footprint in the same shoe after a molded insole and rocker bar were used.

THE DAILY FOOT EXAMINATION

The person with diabetes is advised to check his or her feet every night before bed. Localized redness, localized heat, and localized callus formation are all good indications of stress. If any of them is progressive, it means that the patient is walking too much or wear-

FIGURE 51-21. Special shoes or modifications to regular shoes can change high-pressure areas (right) into a more acceptable pattern of normal pressure distribution (left).

ing the wrong kind of shoe. Small areas of increased surface temperature that are still present the next morning represent inflammation. Persons with insensate feet should remove their feet from under the covers 20 minutes before arising for the day. After this time has passed, the temperature of the pedal skin should be evaluated. Localized, elevated skin temperatures greater than 3–4°F can be detected with a little practice. These elevated temperatures of the foot in the morning, before the first steps are taken, are significant. Any finding of significantly increased surface skin temperature should be evaluated by a foot specialist.

The Open Ulcer

If the person with diabetes finds a wound during the daily inspection, he or she must communicate its presence to the foot care team as soon as possible. In addition to the three previously reviewed ways in which the skin may be broken by mechanical force, it may also be damaged by burns, frostbite, ingrown toenails, or during attempts at self-care, such as the cutting of corns. The result of any one of these is an open wound that may lead to infection. At this point, in most cases the condition is correctable. After a few days of rest with pressure eliminated at the site of injury, normal healing will occur. However, in the absence of normal pain thresholds, many people continue to walk on a wounded foot. Infected tissue fluids are squeezed into deeper areas until bones, joints, and tendon sheaths are involved. Now, with spreading cellulitis and deep abscesses, the person seeks medical attention. Unfortunately, serious problems associated with the diabetic foot occur after the skin is broken and a wound or ulcer forms.

In a survey of causal factors that resulted in lower extremity amputation in diabetic patients, Reiber and associates showed that 84% had foot ulceration as the initial pathology.⁴² It is important to prevent the wound or ulcer, but it is absolutely essential to concentrate on the care and healing of the foot after it is wounded. Much of the reputation for nonhealing wounds on the feet of persons with diabetes has emerged because such wounds have gone undetected or are allowed to progress with each step for months or even years.

ACUTE CARE

Persons with normal sensation automatically do the right thing whenever they have a wound on the foot. Their intact pain sensation regulates their activity every second the injury is present. These persons will not only avoid stepping on the injured extremity, but they will not move the injured part. The absence of direct pressure and movement allows uninterrupted healing, even though the patient remains otherwise active.

In the absence of pain sensation, it is almost impossible for an active person to avoid at least occasional moments of pressure on, or movement of, the wounded part. One unguarded step may undo the immune system's localization of infection that it has taken hours or days to develop. Successful treatment of a wounded insensate foot depends on the patient's and physician's ability to provide an environment that protects the foot as well as pain sensation does in a normal foot. The wound must not be subjected to weight bearing, and the joints, tendons, and soft tissues should be immobilized to restrict the extent of inflammation and infection.

The physician must feel the skin around the ulcer. If it is hot and red, the prognosis for healing is good. If it is cool, bluish, or

dusky, the limb needs careful evaluation for vascular competence, and it may be a candidate for revascularization, angioplasty, or possible amputation. All necrotic tissue and callus should be debrided from the wound site.

All foot wounds should be probed with a sterile instrument such as a nasal sinus probe to reveal any sinus tracts. The presence of a tract is often masked by granulation or necrotic tissue. Gentle insertion of the sinus probe in several parts of the wound from various angles will reveal the presence of the tract. Grayson and colleagues found in a study of 75 patients that probing for osteomyelitis had a specificity of 85% and a sensitivity of 66%.⁴³ The predictive value of probing for osteomyelitis was 89% when bone was felt. However, if bone is not felt, osteomyelitis cannot be ruled out. Probing compares very favorably in sensitivity and specificity to radiographic and radionuclide studies. Grayson and coworkers defined bone contact as a gentle probing resulting in the palpation, as felt through the probe, of a solid, often gritty, structure without intervening soft tissue.⁴³ Early detection of the bone can prevent further destruction by the organism and can often reduce the length of antibiotic therapy. The presence of osteomyelitis requires prolonged antibiotic courses. Probing should not be used as a diagnostic tool when the bone was exposed as the result of surgical debridement. If the opening of the wound on the foot is narrow in proportion to its depth, it should be opened. Dead material may be removed and the wound lightly packed.

A new ulcer or infection may need immediate bed rest and antibiotics. Many publications in the past have contended that all persons with foot infections and diabetes must be hospitalized. However, a prospective study by Lipsky and colleagues has found that diabetic patients with non-limb-threatening infections can be successfully managed on an outpatient basis.⁴⁴ If outpatient management is selected, the principles of controlling pressure and motion must be addressed. Patients with foot infections or severe peripheral vascular disease can be managed with posterior splints or other special protective devices such as have been described in detail by Hampton and Birke.⁴⁵

When the acute phase has subsided (with alleviation of fever and swelling), the ulcer may be classified as chronic, and the foot may be treated by providing a plaster cast for ambulation. No topical medication presently available is so beneficial that it obviates the use of devices such as casts to apply it. In the case of insensitive feet, there is an additional reason for treatment in a plaster cast, namely that patients on bed rest will rarely rest their feet completely. In the absence of pain, even in a hospital setting, patients will get out of bed and go to the bathroom and walk on the infected foot. Hospital personnel are often unaware of the risks of allowing a neuropathic patient with a foot wound to ambulate to the bathroom. In a plaster cast, the foot is protected and patients are free to walk a little and be independent.

The Total Contact Cast

The results of several clinical studies of the effectiveness of total contact casting have been published within the past 15 years. It remains the most reliable method for the treatment of these wounds. Several studies now relate that ulcers that have been present for months to years can predictably be healed within 8 weeks with weight-bearing relief provided by these specialized casts.⁴⁶ Longer healing times have been attributed to severe compromise to the vasculature or poor patient compliance.⁴⁷

Sinacore and associates were able to heal 82% of plantar foot ulcers in an average of 44 days, and found the technique to be far more reliable than conventional wound management.⁴⁸ With casting, Helm and colleagues healed 73% of patients in an average of 38 days.⁴⁹ Walker and coworkers healed 80% of patients in 44 days.⁵⁰ Most recently, Meyerson and associates were able to heal 90% of patients in an average of 39 days.⁵¹ Location and size of the ulcer correlated with the time it took to close these wounds. Larger ulcers took longer to heal. Forefoot ulcers healed in 30 days, and more posterior plantar ulcers took an average of 63 days to close.

The safe criteria for treatment in a plaster cast are: (1) only feet with adequate blood supply (warm around the wound) should be casted; (2) wait until the infection is localized and systemic symptoms have subsided (e.g., fever, tender glands in the groin); (3) make sure the wound is wide open so there is no danger of skin closing over and leaving a deep pocket of infection; and (4) keep in touch with the patient and remove the cast if any new or recurrent symptoms are noted.³⁵

The first cast is usually removed and casting reapplied after 7 days because the limb always shrinks from loss of edema as soon as it is immobilized. If there is obvious swelling at the time the cast was first applied, it should be changed even earlier, because a loose cast is liable to move around and produce friction blisters. The second cast may often be left on for 2 weeks without significant loosening. Never leave a window in a cast. The edges of the window cause shear stress on the tissues that bulge through the window.

The technique for casting does require some practice to lower the risk of secondary complications. The technique is as follows:

1. The patient lies face down with the knee flexed at a right angle and the foot horizontal.
2. The ulcer is covered with a gauze dressing of approximately 1/16-inch thickness held by paper surgical tape (Fig. 51-22).
3. A tube of stockinette covers the foot and leg. If creases form at the bend in front of the ankle, they are slit and allowed to overlap, and taped to avoid any ridges.
4. Orthopedic felt (1/4 inch thick) is used to cover both malleoli and the navicular tuberosity, and a strip of felt is applied anteriorly from top to bottom to facilitate removal of the cast. All felt is beveled at the edges and held with adhesive tape (Fig. 51-23). A layer of foam rubber encloses the toes and metatarsal heads (Fig. 51-24). Thin layers of cast padding are applied under the top edge of the cast and around the heel.
5. A single roll of Gypsona or other very fine plaster bandage is very loosely applied around the foot and leg (Fig. 51-25). It is then rubbed continuously and vigorously into every hollow and around every prominence of the limb until the plaster has set. This inner layer of plaster bandage will be eggshell-thin (consisting of only two or three layers of plaster fabric). The hands of the practitioner who applies it must keep moving constantly. In particular, the plaster on the sole of the foot must be in close contact with every contour of the sole with no padding in between. Padding between the sole of the foot and the sole of the plaster allows movement of the leg in the cast when weight bearing.
6. Once the inner layer of plaster has set, slabs of plaster splint may be applied over it, up and down the posterior calf and sole, and from side to side of the calf under the heel (Fig. 51-26). These may be applied fast and held by encircling plaster or fiberglass bandages; the critical inner layer is already formed. By keeping the leg vertical with the knee flexed, it is easy to

FIGURE 51-22. Gauze dressing over ulcer is secured by paper surgical tape.

FIGURE 51-24. Malleolar pads can be seen through the stockinette. A 1-1/2-inch-wide strip of 1/4-inch felt protects the crest of the tibia and facilitates cast removal.

FIGURE 51-23. Edges of felt pads over malleoli are beveled. Pads are held by paper surgical tape.

FIGURE 51-25. After the eggshell-thin, intimate first layer has set, slabs (five layers of plaster splint) are applied as described in the text to provide support to the cast, but prevent excessive anterior build-up of plaster, thus easing removal.

FIGURE 51-26. Assistance is required to maintain ankle at 90 degrees during cast application. Toes are held in extension to prevent toe-ground contact later during walking.

keep the ankle at right angles and air is free to circulate around the cast.

7. A thin 1/4-inch plywood sole plate can be laid on the plaster sole, and bunched plaster tucked into the hollows between plaster and wood (Fig. 51-27). Finally, a rocker is applied just behind the center of the sole over the plywood (Fig. 51-28). A rubber heel on a 1/4-inch plywood sole plate is satisfactory (Fig. 51-29).
8. No weight bearing is allowed for 24 hours (Fig. 51-29).
9. The patient is told to report back if the cast begins to feel loose or if pain or fever develops. The cast should then be removed and a new one applied if the only problem is loosening of the original cast. Such an event usually just serves to reassure patient and physician that all is going well.

THE NEWLY HEALED FOOT

When an ulcer has finally epithelialized, the problem is no longer one of infection; it is not necessary to keep the patient in bed or in a cast. However, the foot is not yet completely healed, and walking has to be carefully graded because the scar has not consolidated and the tissues are still friable. When a healed ulcer breaks down

FIGURE 51-27. A 1/4-inch plywood sole plate is placed from the heel to the metatarsal heads to prevent localized pressure under the walking heel. Gaps between plywood and cast should be filled with plaster.

again, it usually occurs in the first month after healing. This has often been attributed to a recurrence of infection, but the real reason is commonly shear stress.

Shear Stress

In mechanical terms, normal stress refers to forces that are at right angles to a surface. Shear stresses are parallel or oblique to the surface. In the sole of the foot, normal stresses tend to compress the tissues between the skin and bone. Deposits of fat are flattened, and forces are redistributed and dispersed to prevent localized high pressure. This process is less efficient when normal tissues are destroyed by ulceration and are replaced by scar tissue. However, the difference is not of great consequence.

Shear stress is a different story. The skin of the sole is attached to the bones of the foot by a complex web of fibrous and elastic bands that allow differential movement of the skin over the bone in a well-defined manner. At rest or under compression, the

FIGURE 51-28. The rubber heel is placed behind the center of the plywood sole plate.

FIGURE 51-29. No weight bearing should be permitted for 24 hours after casting.

vertical fibers of the sole are slack and loose. When a horizontal thrust is applied to the foot, as when one begins to run or stop suddenly, or when resisting in a tug-of-war (Fig. 51-30), the skin tends to grip the ground and the bones move on the skin until the vertical fibers become oblique, or almost horizontal, and they are then subject to great tension. They have a limited capability to stretch, and after a certain point can yield no more. At that point, either the body moves in relation to the foot or the foot slides along the ground.

The beauty of the normal structure is that during normal activity, all of the restraining fibers of the skin have a similar ability to stretch or to change their obliquity, so that the strain between skin and skeleton is distributed evenly and the tissues can usually handle all the stress they are subjected to. The trouble with a recently healed ulcer is that the flexible elastic sole tissue is replaced at one point by a solid, inflexible scar. The skin at that point cannot move in relation to the bone. What makes this dangerous is the fact that the rest of the skin of the sole retains its normal mobility. Thus when the foot transmits the shear stress of walking, the only restraint is the single small area of adherence, so the shear stress that is ordinarily taken up by some 15 square inches of normal fibers is now taken up by 1 square inch of a new, weak mass of scar tissue. The predictable result is that the newly formed tissues are torn. A hematoma forms under the new skin. The damage is repeated with continued walking until the wound breaks down again.

FIGURE 51-30. A. Shear stress in normal intact skin. The continuous network of fibrous and elastic tissue withstands the stress. B. Shear stress in presence of scar from a recently healed ulcer. The scar forms a fixed point in the fibrous supportive network. Stresses cause tearing around the junction of mobile and fixed parts of the sole.

THE MANAGEMENT OF NEWLY HEALED PLANTAR ULCERS

Several simple rules should be followed to minimize the recurrence of foot ulcers:

1. The patient must understand the problem; otherwise he or she will make no real attempt to limit activity.
2. Shear stress occurs maximally with fast walking, quick starts and stops, and when making long strides. It also occurs with extension of the toes at the metatarsophalangeal joint when the foot bends at the ball of the foot in the propulsive phase of gait.
3. For the first few weeks after an ulcer heals, the patient should walk as little as possible, slowly and with short steps, preferably with a rigid-soled shoe.
4. Friction between the skin of the sole and the insole of the shoe must be minimized. The inner layer of the insole should be slick and slippery (leather or nylon, rather than rubber or exposed Plastazote). Talcum powder, silicone, or a double layer of socks helps to minimize the extent to which the skin of the foot sticks to the shoe.

SURGICAL INTERVENTION

Elective surgery on the diabetic foot is mainly directed at the prevention of localized pressure and shear. If for any reason it is difficult to avoid high stress to a single aspect of the foot, even with well-fitted shoes, then a foot surgeon should be consulted. Clawed toes or hammer toes may be straightened to avoid stress on the tip

of the toe or on the dorsal aspect of the interphalangeal joint. Bunions and hallux valgus may need correction. If one metatarsal head is prominent on the sole and is shown to be under undue stress during walking in a well-fitted shoe, it may be useful to do an osteotomy at its neck to allow the head to move into alignment with the other metatarsals. Less often, a metatarsal may be shortened to bring it into line with other already shortened metatarsals. Rarely should a metatarsal be removed. Although it allows the ulcer under it to heal, its removal decreases available weight-bearing surface and increases the stress under other metatarsals and creates new problems.

Sometimes a foot may have an imbalance, such as a foot drop or inversion. If such an imbalance or deformity can be corrected surgically by tendon transfer or by an osteotomy, it may avoid the need for custom-made shoes or braces on a permanent basis.

NEUROPATHIC FRACTURES

The definition of a "Charcot's" fracture has evolved over time. Jean Martin Charcot described arthropathy that developed without known cause in patients with *tabes dorsalis* or other neuropathies.⁵² The term *Charcot's fracture* is now used to describe a fracture in the presence of neuropathy. It should also be extended to include cases in which the tarsus collapses due to ligamentous failure, but no fracture can be identified radiographically.

When confronted with a neuropathic fracture, a physician who rarely sees them can be misled to make an incorrect diagnosis of infection with cellulitis. Frequently, patients with neuropathic fractures in the feet retain this diagnosis of infection for months before the correct diagnosis of fracture is made.

CASE REPORT

A 49-year-old African-American male was referred to the foot clinic by his family physician. The patient had refused to consent to having his left foot amputated. He wanted a second opinion. He had been admitted to his local hospital for foot infection 3 months earlier. No open foot wound had been present prior to his admission at that time.

Three weeks after that admission, radiologic studies were made of the foot. A radiologist interpreted the films as showing signs of osteomyelitis. An exploratory surgery was performed and a bone biopsy was taken. No abscess was found. The bone and soft tissue samples showed no bacterial growth when cultured.

At no time during this hospital stay was the patient advised not to walk on his foot. After surgery the foot became more red and swollen. A second exploratory surgery was performed and again all cultures were negative. Two weeks later the patient was advised to have the foot amputated.

On presentation to the foot clinic he presented with a dorsal foot wound 2 × 10 cm in size. It showed no sign of purulence or necrosis. The foot was red, hot, and swollen. Radiologic studies revealed an anterior-medial pillar Charcot's fracture.⁵³ He was placed in a rigid posterior splint. He was admitted to the hospital on complete bed rest with bedside commode and orders that he could only be transferred from the bed by wheelchair. He was treated with wet-to-damp normal saline dressings and IV antibiotics. The skin wound healed in 3 weeks. Also by then most of the edema and erythema had subsided. A total contact cast was applied. He was then discharged from

the hospital and antibiotics were discontinued. The cast was changed weekly for 4 weeks. After that casts were changed every 3 weeks. Casting was continued until the surface skin temperature was within 2°C of that of the other foot.

After 3 months of casting, a custom-molded foot-bed was constructed and placed in an off-the-shelf double upright, orthopedic walking boot with Velcro straps. He used this boot for an additional 3 months. He was then gradually rehabilitated from the boot to a custom-molded orthotic device in an extra-depth oxford shoe. He has been maintained in this shoe for the past 10 years. He has occasional small foot injuries. These are quickly addressed in the foot clinic.

The key to success in the treatment of neuropathic joint deformity is early diagnosis. It is frequently at the regular routine checkup of the foot that early cases are detected. This includes the patient's own nightly foot examination. The most constant sign of early joint damage is a patch of localized heat. If the patient feels his or her own feet each morning, he or she will quickly note this hot area, often on the medial aspect of the midfoot. At that stage the x-ray may show early fragmentation of the navicular, the medial cuneiform, or the head of the talus. When any increased heat, redness, or swelling is discovered in an insensitive foot with no open wound present, neuropathic fracture must be considered first.

When confronted with a red, warm, swollen foot on a diabetic patient, and no open wound can be found, the clinician should assume that a Charcot's fracture is present until an alternative diagnosis is conclusively proven. Even if radiologic studies fail to show the presence of a fracture, if the surface skin temperature remains hot, the foot must be immobilized and weight bearing should be supported until the temperature returns to normal.

Harris and Brand described patterns of tarsal disintegration.⁵³ Any fracture in the presence of neuropathy could be classified as a Charcot's fracture, but they have identified five patterns unique to insensate foot. They are:

1. **Posterior Pillar**—This is a fracture of the posterior portion of the calcaneus. With time, the posterior portion of the fracture is pulled proximally by the Achilles tendon.
2. **Central Body**—This fracture occurs at the inferior part of the talus where it articulates with the calcaneus. Initially, it does not involve the ankle joint. If the person continues to walk on the fracture, the bottom of the leg will get progressively closer to the ground by passing medial to, lateral to, or through the body of the calcaneus.
3. **Anterior Pillar (medial)**—These fractures occur in the head of the talus or at the talar-navicular articulation. They progress to form a rocker-bottom foot or a large exostosis under the medial arch.
4. **Anterior Pillar (lateral)**—These are the rarest pattern and involve the calcaneal-cuboid joint. The foot quickly develops a rocker-bottom shape.
5. **Tarsal/Metatarsal**—These fractures are difficult to diagnose early in their development because they begin as a fracture in the first cuneiform, and radiologically the only evidence is a small increase in the space between the bases of the first and second metatarsals. With continued walking, the fracture extends across the bases of all of the metatarsals. A bony ridge often forms across the top of the foot.

Inflammation results in hyperemia. Prolonged hyperemia can result in local bone absorption. In normally sensate individuals, the

pain associated with inflammation will regulate their activity. In the absence of protective sensation, with continued unprotected use, the injury will attain a duration and intensity of inflammation not seen in normal individuals. This degree of inflammation results in the spread of injury, both from the repetitive stress of walking on an open wound and in the case of neuropathic fracture. Successful management of these injuries requires the cessation of the progression of inflammation through relief of weight bearing and immobilization of joints and tendons.

CONCLUSION

The vast majority of lower extremity amputations can be avoided. To accomplish this on a national scale, the medical community must embrace changes in its current approach to this epidemic. The physician must learn to appreciate the unique environment in which neuropathic injuries occur. A multidisciplinary team is needed to successfully manage diabetic foot problems. Injury prevention through education, appropriate footwear, and regularly scheduled clinic visits should be at the heart of such a program. Members of this team should have a knowledge of psychology, social intervention, patient education, footwear and orthoses, biomechanics of the lower extremity, neuropathic wound and fracture care, and diabetes management. The person with diabetes is a patient for life. Professionals who accept the challenges of helping them should be willing and able to provide treatment and rehabilitation for the rest of their patients' lives.

Diabetes and the GI System

Francisco J. Baigorry

Jamie S. Barkin

Diabetes mellitus affects the entire gastrointestinal system. Therefore as expected, patients with diabetes mellitus are prone to develop a spectrum of clinical symptoms directly related to the effects of diabetes mellitus on their GI tract. This chapter will review these entities, discussing both clinical and pathologic features. In addition, multiple organs may be involved and therefore symptoms may overlap and present a complex picture.

ESOPHAGUS

Esophageal Motor Dysfunction

Esophageal motor dysfunction has been well-documented in patients with diabetes mellitus since Mandelstam and Lieber's cineradiographic study in 1967.¹ They described reduced or absent primary peristaltic waves and occasional tertiary contractions in 12 of 14 diabetic patients with neuropathy. Subsequently, these abnormalities have been characterized using manometry, radiography, and scintigraphy.

Overall, manometric abnormalities occur in over 50% of patients with diabetes. These include increased numbers of spontaneous and repetitive contractions, aperistaltic contractions, reduced lower esophageal sphincter pressure, reduced amplitude of pharyngeal and esophageal contractions, and increased duration of peristaltic contractions. Studies using high-fidelity manometric recordings have demonstrated an aberrant pattern of multi-peaked peristaltic pressure complexes in the smooth muscle segment of the esophagus in patients with evidence of diabetic autonomic neuropathy (DAN).² This finding was uncommon in patients with diabetic autonomic neuropathy or in other patient groups. However, the multi-peaked peristaltic waves moved food boluses through the esophagus effectively, and the diabetic subjects studied lacked clinical symptoms. Other manometric studies have corroborated that despite the demonstration of esophageal manometric abnormalities, clinical symptoms such as dysphagia, chest pain, or heartburn are usually very mild or absent.³ This may be secondary to an underlying diabetic sensory neuropathy. Therefore, the functional significance of these manometric abnormalities remains unclear.

Video radiography and nuclear scintigraphy are more useful screening tests for evaluating disturbances of esophageal motility. Impaired esophageal transit and emptying was demonstrated in up to 35% of patients with both type 1 (T1DM) and type 2 diabetes mellitus (T2DM).⁴⁻⁶ Another prospective study demonstrated delayed esophageal emptying in 34 of 50 type 1 diabetic patients. De-

spite the demonstration of delayed esophageal emptying, most subjects remained asymptomatic. Again, whether this is related to impaired sensory perception or a lack of symptoms of physiologic significance is unclear. However, these patients probably have an increased risk of stasis, including localized pill ulceration of the mucosa and delayed drug absorption.

Gastroesophageal reflux also occurs more often in patients with diabetes. Diminished lower esophageal sphincter pressure has been demonstrated manometrically, and 24-hour pH monitoring has shown that reflux occurs more frequently in diabetic patients than in controls. Using ambulatory pH monitoring, 9 of 20 persons with diabetes had abnormal acid reflux. It was suggested that delayed gastric emptying may have contributed to the reflux. Neural impairment appears to play a significant role in the pathogenesis of esophageal dysmotility. There is a strong correlation between the presence of autonomic and peripheral neuropathy and abnormal esophageal motor function in diabetic patients.² Some studies have shown that the duration of disease may correlate with the severity of the neuropathy, yet others have found no significant correlation. An interesting association is the proposed strong relationship between psychiatric illness, especially depression and generalized anxiety, and esophageal motility disturbances, which was independent of the presence of neuropathy.⁵

Physiologic and histologic evidence supports neural dysfunction rather than esophageal smooth muscle impairment as a primary factor in diabetic patients with esophageal motility disturbances. Animal studies have demonstrated intramural neural mechanisms for the control of esophageal peristalsis. The on-contraction (A wave) is controlled by cholinergic excitatory nerves, and the off-contraction (B wave) is elicited by noncholinergic, nonadrenergic inhibiting nerves. Therefore, A waves are atropine sensitive whereas B waves are not. Loo and coworkers demonstrated an aberrant manometric pattern of multi-peaked peristaltic pressure complexes in diabetic patients with DAN.² These complexes were converted to monophasic waves by administration of a small dose of atropine, whereas administration of edrophonium exaggerated the number and amplitude of these complexes. They concluded that neural dysfunction caused the aberrant motility pattern. Evidence of a neurologic rather than a myopathic disorder includes histologic studies that show abnormalities within prevertebral ganglia, including Schwann cell loss and Wallerian degeneration, whereas myenteric plexus and esophageal musculature remain intact.⁴

Also, monilial esophagitis, reflux esophagitis, and both benign and malignant strictures should be excluded. Obviously, one must exclude a cardiac source of the chest pain and esophageal mucosal disease prior to ascribing it to an esophageal motor disorder.

Monilial Esophagitis

Monilial esophagitis is most commonly found in patients with underlying malignancies, cirrhosis, or reduced immune response. In addition, diabetic patients are predisposed to monilial esophagitis. These patients usually have uncontrolled diabetes or are receiving immunosuppression after undergoing renal transplantation. Symptoms of monilial esophagitis include dysphagia or odynophagia that may be so severe as to prevent swallowing. The dysphagia is usually for solids, but may involve liquids, especially if they are hot. Radiographic findings of candidiasis on barium swallow include a shaggy outline of the esophageal wall or frank ulcerations, intermucosal filling defects, nodular formations, or a combination of these entities. These findings are usually more prominent in the middle or lower third of the esophagus. Esophagoscopy often reveals a yellowish, cheesy exudate on the mucosa, which is erythematous and friable but may be ulcerated. Esophageal brushings reveal yeast forms. Cultures for *Candida* may reveal the organisms, but are unable to distinguish whether there is colonization or invasion of the esophageal mucosa. Biopsies of the esophagus may show buds or hyphae invading the mucosa. Serum agglutinating titers may be valuable when the titer is >160 , which usually correlates with severe infection and tissue invasion.

Treatment for monilial esophagitis is dependent on the severity of the infection. Mild cases can be treated with luminally active agents such as nystatin, clotrimazole, or oral amphotericin. In symptomatic or refractory cases, oral medications that reach the systemic circulation such as ketoconazole or fluconazole can be used, and a single dose has been reported to be curative. Fluconazole appears to have fewer side effects than ketoconazole and may be better absorbed in the patient with achlorhydria. Both of these agents may interfere with the metabolism of other drugs, for example, coumadin and cyclosporine. The use of intravenous therapy for monilial esophagitis with amphotericin B and flucytosine is usually reserved for granulocytopenic patients with fungal esophagitis, who have a higher risk of disseminated disease.⁷

STOMACH

Gastroparesis Diabeticorum

Clinical Features

Gastric neuropathy secondary to diabetes was first described by Rundles in 1945⁸ and became widely recognized after 1958 when Kassander first used the term **gastroparesis diabeticorum**. Although gastric motor abnormalities can be found in approximately 20–30% of diabetic patients, most studies show very little correlation with clinical complaints. Symptoms predominantly result from (1) gastroesophageal reflux with heartburn and halitosis, (2) gastric stasis with early satiety, pain, nausea, vomiting, and/or anorexia, and (3) distension with hiccups. These are most pronounced postprandially and occur intermittently, punctuated by symptom-free intervals. There may be a deterioration and lability of glycemic control due to unpredictable gastric emptying, resulting in hypoglycemic episodes. Moreover, in some diabetic patients

with gastroparesis, the only symptom may be poor glycemic control, without any gastrointestinal symptoms. So gastroparesis can be present without any symptoms, just as myocardial ischemia can occur without symptoms in diabetic patients.¹⁰ Rarely gastric stasis may result in formation of gastric bezoars and bacterial overgrowth.

Pathophysiology

The etiology of delayed gastric emptying due to diabetes mellitus remains unclear. Vagal neuropathy has been proposed because of its role in the reflexes that regulate gastric motility and emptying. In support of this theory, postvagotomy patients demonstrate similar radiographic and clinical findings to patients who have diabetic gastroparesis. Physiologic evidence of vagal dysfunction has been demonstrated by decreased acid output in response to sham feeding and elevated gastrin levels in diabetic patients with gastroparesis.¹¹ Pharmacologic evidence also exists in that antral contractions are directly stimulated by metoclopramide and bethanechol and are inhibited by atropine in affected patients. Support also rests on histologic abnormalities of the vagus, including lymphocytic infiltration, irregularity or disruption of nerve fibers, and crowding of Schwann cell nuclei, as well as segmental demyelination, that are seen in patients with gastroparesis diabeticorum.^{6,12} Evidence against vagal neuropathy is the lack of acceleration of early gastric emptying seen in postvagotomy patients, but not in diabetic patients with gastroparesis. In addition, after surgical vagotomy, there is preservation of the differential rate of emptying of liquids and solids, which is occasionally lost in diabetic patients. Finally, Yoshida and collaborators found no histologic abnormalities of the myenteric plexus or abdominal vagus in diabetic subjects with or without gastroparesis when compared to controls. Coordinated relaxation of the pylorus is essential for chyme to move efficiently from the antrum to the duodenum. Pylorospasm has been reported as a cause of delayed gastric emptying in diabetic patients.^{10,13}

Hormonal factors are important in the control of gastric emptying. Motilin, a gut polypeptide, is capable of initiating an interdigestive migrating motor complex (IMMC). Diabetic patients have higher basal levels of motilin,¹² which decrease in response to insulin administration.¹⁴ In normals, metoclopramide-induced IMMC was associated with increased plasma motilin levels that were decreased in diabetic patients.¹⁵ In addition to motilin, diabetic subjects have altered secretion of pancreatic polypeptide, somatostatin, glucagon, and gastrin.¹⁶ Despite these abnormalities, the role of hormonal imbalance in diabetic gastric dysfunction remains unclear.

Several other factors in diabetes may affect gastric motility. These include the level of glycemic control and the occurrence of ketonemia, acidosis, and electrolyte disturbances. Acute hyperglycemia decreases emptying of liquid meals and may contribute to a generalized gastric atony. Acute gastric dilation is frequently seen in patients with diabetic ketoacidosis and may be a result of hyperglycemia, hyperglucagonemia, electrolyte imbalance, ketonemia, acidosis, or an acute reversible autonomic neuropathy. In summary, the etiology of diabetic gastric dysfunction is unclear, but it likely results from an alteration of several interrelated factors.

Diagnosis

Gastroparesis diabeticorum should be suspected clinically if the patient has upper GI tract symptoms or if their diabetes becomes difficult to control without explanation. Roentgenographic and nuclear medicine solid phase gastric emptying studies assist in diagnosis. Contrast studies will likely demonstrate advanced

disease, whereas early disease and its quantification are measured by gastric emptying studies. The most common radiologic feature on upper gastrointestinal series is sluggish, ineffectual, and irregular gastric peristalsis. This often may be accompanied by the presence of a significant amount of solid gastric residue despite the preceding 12-hour fasting period. Other features commonly noted on barium study include elongation of the stomach, giving it a sausage-shaped configuration, significant retention of ingested barium (grossly defined as 50% or more of the ingested barium present on the 30-minute follow-up film), and duodenal bulb atonic dilatation without evidence of organic obstruction (Fig. 52-1). The pylorus is widely patent, although it may be necessary for the examiner to externally compress the abdomen in order to force barium into the duodenum to demonstrate pyloric patency.

Radioisotope gastric serial scintiscanning studies allow quantification and accurate measurement of both liquid- and solid-phase emptying. The method for measuring solid-phase emptying uses *in vitro* labeled egg albumin and is usually abnormal in patients with diabetes mellitus and gastroparesis (Fig. 52-2). Conversely, gastric emptying of liquid meals is often normal. The emptying rate of the indigestible solids seems to demonstrate the most profound abnormalities of gastric emptying in patients with gastroparesis diabeticorum.¹⁷ In a healthy control group, most orally ingested markers emptied from the stomach by the fourth postprandial hour, and all ten markers had emptied by 6 hours in 45 of 46 trials. In contrast,

FIGURE 52-1. Upper GI barium study, showing significant solid residue after an overnight fast in an elongated sausage-shaped stomach with retained barium without evidence of mechanical gastric outlet obstruction.

indigestible solid markers were retained in the stomach 6 hours after the meal in 50% of the diabetic patients studied. The gastric emptying rate has been measured by carbon-labeled breath test and compared with scintiscanning studies.¹² ¹³C labeled food is absorbed from the intestine as it is emptied from the stomach, and then expired from the lungs where it can be measured. There seems to be good correlation between the results of the breath test and the scintiscanning test.

Manometric studies of the stomach demonstrate diminished proximal stomach and antral motor activity as well as an absence of gastric interdigestive motor complexes in patients with gastroparesis diabeticorum.¹⁸ Mearin and associates investigated the pyloric activity in diabetic patients who had recurrent nausea or vomiting without evidence of mechanical obstruction.¹⁹ The duration of their total pyloric activity before and after meals was found to be significantly greater than in controls. Further, episodes of unusually prolonged pyloric activity and intense tonic contractions, so called pylorus spasms, were observed in 14 of 24 diabetic patients versus only one control. They concluded that pyloric dysmotility is part of the widespread disruption of gut motility that affects patients with diabetes. Its pathophysiologic and clinical sequelae are undetermined.

Gastric contractions are normally coordinated by slow waves that migrate distally through the body and antrum of the stomach at a rate of 3 cycles per minute (cpm) in humans.²⁰ These can be accurately recorded by electrodes placed either on the serosal surface of the stomach or cutaneously.²¹ The resulting electrogastragram (EGG) can detect gastric arrhythmias which are present in disorders such as diabetes mellitus, nausea and vomiting in pregnancy, anorexia nervosa, and motion sickness.²²⁻²⁵ Interestingly, these arrhythmias can be created in normals by injection of large doses of glucagon.²⁶ Good correlation has been obtained between symptoms and EGG findings both before treatment and after clinical improvement with directed therapy.^{27,28} Although this examination is not widely available, it appears to be promising as a diagnostic test and may be useful for clinical monitoring after treatment.

In summary, the normal emptying of digestible solids from the stomach is dependent on antral motor function, whereas liquid emptying is dependent on the gradient between proximal stomach and duodenum. Diabetic patients with symptomatic gastroparesis do not empty liquids significantly differently from normal patients, whereas digestible and nondigestible solids empty significantly more slowly than normal. The slow emptying of nondigestible solids occurs because of abnormalities of the IMMC. The IMMC is normally associated with a cyclically appearing caudally migrating muscular contraction that acts as a janitorial service to sweep the stomach and upper small bowel of nondigestible products and bacteria. A loss of antral phase three of the IMMC has been found in diabetic patients.²⁹ Abnormalities of this function may lead to development of gastric bezoars and bacterial overgrowth. The pylorus is especially important in regulating gastric emptying of solids, and pyloric dysmotility may contribute to delayed solid-phase emptying that affects some patients with diabetes mellitus. Finally, abnormal gastric slow-wave activity has been detected by electrogastrography, which in humans originates in the antrum and may be related to nausea symptoms and a delay in gastric emptying.³⁰

The diagnosis of gastroparesis diabeticorum requires exclusion of other causes of gastric dysfunction, including functional and mechanical obstruction. Functional disorders that may mimic gastroparesis diabeticorum include parasympathetic loss, such as surgical vagotomy; destruction of the vagus from pulmonary,

FIGURE 52-2. Delayed emptying on solid-phase nuclear gastric emptying scan in a diabetic patient with gastroparesis.

esophageal, or gastric malignancy; and drug-induced motility dysfunction. The most common drugs include tranquilizers, anticholinergics, ganglionic blocking agents, and tricyclic antidepressants. Symptoms similar to gastroparesis diabeticorum may also be a consequence of gastric mucosal disease, such as peptic ulcer disease, tumor or mechanical obstruction such as pyloric stenosis, or cicatrix.

The diagnostic evaluation of diabetic patients with symptoms suggestive of gastric stasis should begin with upper endoscopy to exclude primary mucosal disease or mechanical obstruction. Parkman and Schwartz found that 55% of their 20 diabetic patients with intractable nausea and vomiting had gastrointestinal disorders other than gastroparesis that could explain their symptoms.³¹ Following exclusion of an anatomic cause of obstruction, further evaluation of gastric emptying with a radioisotopic study should be performed. This work-up provides both anatomic and functional evaluation of the stomach and permits exclusion of other causes of gastric dysfunction. Other diagnostic tests that should be performed are a small bowel series and possibly an abdominal CT, the latter to visualize the pancreas. Unfortunately, there is a very poor correlation between gastric emptying and symptoms (Table 52-1).

Treatment

Treatment of gastroparesis diabeticorum is often difficult because hyperglycemia inhibits gastric motility. Conversely, diabetic control may be more difficult because of the delayed gastric emptying. Our approach is to initiate a liquid diet if the patient is an outpatient, or if hospitalized the patient is kept NPO, and intravenous glucose is administered. Once glucose levels have returned

TABLE 52-1. Gastroparesis Diabeticorum: Diagnosis and Management

Diagnosis

- Suspect gastroparesis in patients with nausea, vomiting, reflux, bloating
- Exclude mechanical obstruction and peptic ulcer disease by performing an upper endoscopy
- Exclude drug-induced mechanical obstruction: anticholinergics, tricyclic antidepressants
- Barium studies are sensitive only in patients with advanced disease; also may show impaired peristalsis, and retained solid gastric residue despite fasting
- Electrogastrogram: not widely available
- Solid phase radioisotopic study
- Consider CT of the abdomen to evaluate the pancreas

Management

- Optimize glucose control
- Low-fat, low-fiber diet
- Four to six small meals daily
- Metoclopramide
- Domeperidone (outside U.S.)
- Cisapride (outside the U.S.)
- Erythromycin
- Erythromycin derivatives (in the future)

to normal, medical therapy is initiated. A low-fat diet (<40 grams per day) and a decreased amount of fiber distributed in 4–6 meals a day may help the symptoms of patients with gastroparesis diabeticorum.¹⁰ Cholinergic agents such as bethanechol and cholinesterase inhibitors such as ambenonium chloride have met with variable success and are often associated with disturbing side

effects. The agents most commonly used for the treatment of gastroparesis diabeticorum are promotility drugs such as metoclopramide, domperidone (outside of the United States), cisapride, and erythromycin. Cisapride, which was also used, has been withdrawn from the U.S. market by the Food and Drug Administration because of drug-induced cardiac arrhythmias. These agents stimulate contraction of the smooth muscle of the gastrointestinal tract.

Although metoclopramide's mechanism of action has not been completely elucidated, actions that may be responsible for its effects include: (1) the release of acetylcholine from intrinsic nerve plexus in muscles, (2) antagonism of dopaminergic and tryptaminergic neural transmission, (3) inhibitory effects of dopamine on gastric motility, (4) facilitation of peristaltic reflexes, (5) direct effect on gut smooth muscle, and (6) inhibition of the central nervous system chemoreceptor trigger zone for vomiting. The mechanism of action of domperidone has not been completely elucidated, but it is believed to promote gastric relaxation and enhanced antral contractility through antagonism of peripheral dopamine receptors.³² Unlike metoclopramide, domperidone does not cross the blood-brain barrier and therefore has no significant effects within the central nervous system (CNS).³³ Erythromycin and other 14-member macrolides are believed to stimulate gastrointestinal motility by mimicking the effects of the gut polypeptide motilin.³⁴

Administration of metoclopramide initially increases the rate of gastric emptying in patients with delayed gastric emptying, as evidenced by decreased gastric volumes, decreased recovery of ingested solid foods, and increased rate of gastric emptying of isotopically labeled test meals.^{35,36} Several clinical trials of multiple-dose metoclopramide therapy have demonstrated improvement in both symptoms and gastric emptying rate.³⁷⁻³⁹ Investigators have noted that a reduction in symptoms was seen in some patients with minimally impaired gastric emptying, suggesting an important role for the antiemetic properties of metoclopramide.^{38,39} However, long-term trials have demonstrated a discordance between diminished motility effects and continued symptomatic relief with this agent.⁴⁰ Unfortunately, adverse effects occur in approximately 20% of patients after metoclopramide administration and most commonly involve the CNS and GI tract. The CNS effects require monitoring of the patient for development of extrapyramidal symptoms, and rarely, Parkinsonian motor disorders and dystonia,⁴¹ which may not resolve with discontinuance of the drug. Additionally, metoclopramide can produce hyperprolactinemia, resulting in breast tenderness and enlargement, galactorrhea, and menstrual irregularities.⁴¹ The usual adult dosage of metoclopramide for the treatment of diabetic gastroparesis is 10 mg, four times daily given 15-30 minutes before meals and at bedtime. Initially, the patient should be started on liquid metoclopramide to facilitate its absorption. Higher doses are often tolerated, but an increased incidence of adverse effects is likely, particularly in the elderly.⁴¹ Lastly, patients with a creatinine clearance <60 mL/min should have appropriate reductions in dosage.⁴¹

Domperidone experimentally enhances gastroduodenal contractility and coordination, and clinically increases the rate of gastric emptying.^{36,42} Similarly to metoclopramide, domperidone treatment in diabetic patients commonly results in early symptom relief, although quantitative improvement in gastric emptying has been only temporary and statistically insignificant.^{27,43} Koch and associates, in an open-label trial, demonstrated normalization of gastric arrhythmias in all six insulin-requiring diabetic patients treated for 6 months with domperidone, 20 mg four times a day.²⁷ The restoration of the normal gastric myoelectric activity (3 cycles/min) occurred despite the persistence of abnormal solid-phase

gastric emptying, but was associated with symptomatic improvement in these diabetic patients. However, this did not normalize their solid-phase emptying rates, demonstrating another discordance between the clinical and physiologic effects of drug therapy for diabetic gastroparesis. In contrast to metoclopramide, domperidone has poor penetration of the blood-brain barrier and therefore CNS symptoms are exceedingly rare.³³ Cardiac arrhythmias do not result from intravenous administration.⁴⁴ The usual adult dosage ranges from 40-120 mg in three to four divided doses; need not be adjusted for renal dysfunction.³³

Erythromycin and the other 14-member drugs that are macrolides stimulate increased gastrointestinal motility by acting as competitive agonists for motilin receptors located predominantly above the ligament of Treitz.⁴⁵ The initial report of the use of erythromycin in 10 patients with diabetic gastroparesis by Janssens and coworkers revealed that 200 mg administered intravenously 20 minutes postprandially markedly improved the severely impaired gastric emptying of both liquids and solids.⁴⁵ In addition, patients receiving erythromycin at a dose of 250 mg orally three times daily before meals for 1 month, showed statistically significant improvement in their emptying of both solids and liquids at 120 minutes after ingestion of a double-isotope test meal. Peeters and associates demonstrated that low-dose IV erythromycin (40 mg) in patients with diabetic gastroparesis induced a premature pattern of contractions that mimicked the naturally occurring gastric phase three of the IMMC.⁴⁶ Larger doses (200-350 mg given intravenously) prompted a burst of rhythmic antral contractions at maximal contractile frequency with no propagation to the small bowel and absent phase one IMMC quiescence. Erythromycin and other macrolides with motilinomimetic properties appear to correct both the interdigestive and postprandial motility defects found in patients with diabetic gastroparesis during short-term treatment. It remains unclear whether these physiologic effects will translate into long-term symptomatic improvement. Preliminary studies suggest that erythromycin derivatives may play a role in the therapy of diabetic gastroparesis without the antibacterial effect of erythromycin.⁴⁷

Our treatment approach in a hospitalized patient with intractable symptoms is to initially use an intravenous bolus of erythromycin or metoclopramide. Peristalsis visualized during endoscopy following drug infusion may predict a successful initial therapeutic response. We generally continue intravenous administration of the drug during progressive liberalization of food intake from liquids to semisolids to solids, switching to an oral prokinetic preparation after solids have been tolerated for 24-48 hours. Improved response may be obtained when these drugs are combined because they act physiologically on different areas of the GI tract.

Surgical intervention for refractory diabetic gastroparesis is rare but should arguably provide a means for gastric drainage, decompression, and a route for predictable nutritional support. Drainage procedures alone, such as gastrojejunostomies and pyloroplasties, have only a 50% success rate.⁴⁸ Reardon and coworkers reported a patient who underwent a pyloroplasty, decompression gastrostomy, and feeding jejunostomy with significant clinical improvement initially, but then suffered a complication due to the jejunostomy tube, which eventually resulted in death.⁴⁸ A feeding jejunostomy, although a valuable tool for nutritional support and glycemic control, is associated with significant complications such as clogging, a "dumping" syndrome related to bolus feedings, and small bowel necrosis due to nonthrombotic occlusion of mesenteric vessels. Alternatively, a percutaneous endoscopically guided

jejunostomy (PEJ) can provide a means of both gastric decompression and jejunal feeding without the inherent risks of surgery.

The prognosis for patients with symptomatic gastroparesis diabeticorum is guarded, since these patients usually have advanced complications of diabetes mellitus. The course of patients with asymptomatic gastric motility disturbances is unknown.

Atrophic Gastritis

The gastric mucosa in diabetic individuals becomes atrophic at an earlier age and more frequently than in nondiabetic patients. As many as 85% of diabetic patients have biopsy-proven partial or complete atrophy of the gastric mucosa.⁴⁹ The gastritis does not appear to be related to the severity or duration of the diabetes, but instead is age related. With advancing age, the frequency of superficial or atrophic gastritis increases.

Studies of gastric acid secretion of diabetic patients have yielded conflicting results. Several studies have reported a decrease in gastric secretion when compared with nondiabetic individuals, whereas others have found no difference in their maximum acid output.^{11,50} One possible explanation is that both hyperglycemia and hyperglucagonemia inhibit gastric acid secretion. Green and associates used sham feeding to evaluate vagal control of gastric acid production compared with pentagastrin stimulation.⁵¹ In contrast to previous findings, a reduced acid secretory response to sham feeding was not consistently found in a diabetic population.⁵² In addition, Gramm and coworkers found that acid secretory responses to homogenized food, infused directly into the stomach of diabetics, as well as maximal acid secretion to parenteral pentagastrin, is normal,⁵² indicating an intact acid secretory capacity. However, in diabetic subjects, the food-stimulated gastrin response was exaggerated, and this may have been sufficient to permit a normal acid response to food.

Antibodies to gastric components are more frequently found in type 1 diabetic patients than in nondiabetic individuals. Circulating parietal cell antibodies have been found in up to 25% of type 1 diabetic patients compared with 8% of controls. Intrinsic factor antibodies occur in up to 8% of people with diabetes,⁵³ and these were especially prevalent in young women with type 1 diabetes. As might be expected with time, latent pernicious anemia appears to be more common in this group, affecting 4–5% of middle-aged and elderly type 1 diabetic patients, especially women.⁵³ Therefore, in type 1 diabetic patients who have peripheral neuropathy, coexisting unsuspected pernicious anemia may be present and should be sought by determining periodic B₁₂ levels.

The role, if any, that *Helicobacter pylori* has in diabetic gastritis is unclear and remains to be further elucidated. There appears to be a greater incidence of *H. pylori* infection in diabetics, which correlates better with duration of diabetes than with the chronological age of the patient. Conversely, there is a decreased incidence of *H. pylori* infection in patients with diabetic gastroparesis when compared to patients with normal gastric emptying.

SMALL INTESTINE

Diabetic Diarrhea

Clinical Presentation

Involvement of the small intestine in diabetics is often symptomatic, resulting in diarrhea. The frequency of diarrhea varied from

10–22% in Feldman and Schiller's study. The syndrome of diarrhea in diabetic patients was first described by Bergen and colleagues in 1936. Characteristically, these patients are young adults (20–40 years old), more often men than women (ratio 3:2), with poorly controlled, longstanding type 1 diabetes occurring a mean of 8 years after the onset of diabetes mellitus.⁵⁴ There is usually coexistent peripheral or autonomic neuropathy. The diarrhea is usually brown, watery, and voluminous, and may be associated with tenesmus. As many as 75% of diabetic patients with diarrhea have documented steatorrhea. Altered small bowel motor function alone, without any concomitant malabsorption disorder, may produce up to 14 grams per day of fat in the stool.⁵⁵ Fecal incontinence may also occur and is distinguished from diabetic diarrhea by frequent stools of low volume, associated with neuropathy of the external and internal^{56,57} sphincter. Diabetic diarrhea can occur at any time, but is often nocturnal and may be associated with soiling and fecal incontinence. It is important to distinguish fecal incontinence from true diabetic diarrhea, the latter presenting with an increased stool volume (>200 g daily). In patients with diabetic diarrhea: (1) defecation may be preceded by abdominal distension and borborygmi, (2) the patient may pass up to 20 or more stools daily, and diarrhea is often worse following meals, and (3) the diarrhea is typically episodic, with bouts lasting days to weeks. These episodes are often followed by weeks to months of normal bowel habits, or occasionally constipation. Interestingly, as time passes the diarrhea tends to become less severe. Even with severe diarrhea, body weight is generally maintained. If weight loss is present, it is usually in association with concomitant gastroparesis or steatorrhea.

Pathophysiology

The pathogenesis of diabetic diarrhea is still not completely resolved and is probably multifactorial. Several mechanisms are proposed to explain the structural and functional pathogenic abnormalities involved in diabetic diarrhea. These include (1) visceral autonomic neuropathy,⁸¹ (2) bacterial overgrowth, (3) bile acid malabsorption,⁵⁸ (4) pancreatic exocrine insufficiency, and (5) electrolyte imbalance⁵⁸ and altered gut hormone production. Overall, it appears that the major contributing factor is the presence of diabetic autonomic neuropathy (DAN).

Several concepts support this postulate. The diarrhea often coexists with other manifestations of DAN, particularly abnormal pupillary responses, impotence, dysfunction of the urinary bladder, anhidrosis, retrograde ejaculation, or orthostatic hypotension. Autonomic dysfunction from causes other than diabetes also result in diarrhea, including vagotomy, sympathectomy, pheochromocytoma, administration of ganglionic blocking agents, and infiltrative processes involving the autonomic ganglia such as amyloidosis.⁶⁰ Previously, the only significant autonomic histological finding was a nonspecific dendritic swelling in the sympathetic prevertebral and postvertebral ganglia, which was often present in diabetic patients both with and without diarrhea. Degenerative histologic changes have not been consistently observed in the intestinal plexuses studied by Meissner and Auerbach in diabetic patients, and the intestinal mucosa, muscle, microvasculature, and ganglia are often normal histologically.⁶¹ Occasionally, there is mild lymphocytic infiltration of the lamina propria.

The mechanism by which DAN plays a role in diabetic diarrhea may involve alterations in ion transport as well as impairment of intestinal motility. First, the loss of autonomic regulation of ion transport, which is secondary to the loss of the α_2 -adrenergic enterocytic receptors, may lead to diarrhea. These α_2 -adrenergic recep-

tors in the small and large intestine enterocytes stimulate sodium chloride absorption and inhibit bicarbonate secretion,^{62,63} resulting in a net influx of fluids and ion. Chang and coworkers demonstrated an impaired adrenergic regulation of mucosal ion transport resulting in a net intestinal fluid secretion in streptozocin-induced chronically diabetic rats with diarrhea.^{63,64} Clonidine, a specific α_2 -adrenergic receptor agonist that enhances mucosal absorption of fluid and electrolytes and inhibits anion secretion, has resulted in decreased diarrhea in uncontrolled trials.^{65,66} The prominent side effects of clonidine such as orthostatic hypotension, sedation, and dry mouth have been less frequently found in diabetic patients who receive this drug. In cases where the use of oral clonidine is associated with side effects significant enough to limit treatment, recent case reports have suggested that topical clonidine may be substituted with a similar benefit in the treatment of diabetic diarrhea, with a less pronounced side effect profile.

Gastrointestinal motor abnormalities also affect the small bowel in diabetic patients. Studies have shown considerable variability in small bowel transit time. Thus both delayed and enhanced motility have been observed in studies using radiopaque markers and hydrogen breath tests.^{67,68} In view of these conflicting findings, it is likely that the pathophysiology of diabetic diarrhea is diverse. A recent study has shown that even though the transit time is often abnormal in diabetics, patients did not necessarily have diarrhea.⁶⁸ It has been suggested that the neuropathic process can induce alterations in the intestinal motility by disturbing the propagation of myoelectric activity.⁶⁹ The presence of rapid transit may result in increased fecal propulsion and diarrhea, or conversely, slow transit may lead to stasis and bacterial overgrowth, promoting diarrhea and steatorrhea via a type of blind-loop syndrome.

The three factors that prevent the growth and accumulation of enteric bacteria in the upper small intestinal lumen are intestinal motility, gastric acid, and immunologic or bacteriostatic intestinal secretions. Alteration of one or more of these mechanisms can result in small intestinal bacterial overgrowth. The delayed small bowel transit observed in diabetic patients can therefore lead to bacterial overgrowth. The pathophysiologic basis is that small bowel bacteria deconjugate bile acids, preventing micelle formation, and result in fat malabsorption, steatorrhea, and diarrhea. Indirect support of this proposal comes from a few reports that describe clinical improvement of the diarrheal syndrome with broad-spectrum antibiotics. Bacteriologic evidence has revealed normal bacterial concentrations in most of these patients. However, these studies did not culture for anaerobic bacteria (i.e., bacteroides, enterococcus, and clostridium) which unlike aerobic bacteria, are capable of deconjugating bile salts more effectively.

The gold standard for the diagnosis of bacterial overgrowth is the proper placement of a jejunal tube and culture of the intestinal aspirate. The normal concentration of bacteria in the upper GI tract is $<10^4$ organisms per mL of intestinal contents. Noninvasive breath tests have also been evaluated as a means to detect bacterial overgrowth. Studies have shown that the ^{14}C xylose breath test has a sensitivity and specificity exceeding 90%, and therefore it has become the noninvasive test of choice in the evaluation of patients with suspected bacterial overgrowth. Two recent French studies have demonstrated the efficacy of antibiotics (norfloxacin and amoxicillin-clavulanic acid) in diabetic patients with diarrhea and bacterial overgrowth.^{70,71}

Bile acid malabsorption has also been suggested as a contributing factor to diabetic diarrhea on the basis of a decreased bile salt pool. However, measuring fecal $^{14}\text{CO}_2$ levels after administering

^{14}C glycocholate revealed that only 15% of diabetic patients with diarrhea had increased fecal bile acid excretion.⁷² In addition, the administration of cholestyramine did not show any therapeutic effects in the majority of patients. Therefore the role of bile acid malabsorption is not clearly established and may be related to accelerated small bowel transit or bacterial overgrowth.

Pancreatic exocrine insufficiency, abnormal colonic motility, anorectal dysfunction, and celiac sprue in diabetics are several other mechanisms that may contribute to diarrhea found in a diabetic patient. In addition, consumption of dietetic foods that contain sorbitol, including sugarless chewing gum, dried roasted nuts, meat products, icings, toppings, dairy products, brown sugar, and beverages, may also result in diarrhea. This may be a confounding factor because many diabetics who consume sorbitol are unaware of its presence in the diet.⁵⁸

Management of chronic diarrhea in diabetics should initially be directed toward correction of the imbalance of fluids and electrolytes, control of diabetes, and restoration of nutrition, and subsequently a search for an identifiable cause of the diarrhea is initiated. Small bowel bacterial overgrowth is treated with oral broad-spectrum antibiotics (see above), to include coverage for anaerobic bacteria, such as metronidazole with a quinolone or cephalosporin with tetracycline. Antibiotics are administered for 1 week of every month on a rotating basis to avoid development of bacterial resistance. Other treatable causes of diarrhea in a diabetic patient are a gluten-free diet for celiac disease, pancreatic enzymes for pancreatic insufficiency, and biofeedback mechanisms, which may be effective in controlling diarrhea secondary to fecal incontinence.⁷³

Often, however, the pathogenesis of diarrhea in the diabetic patient is not clear, and treatment must be directed at alleviating the patient's symptoms. Antidiarrheal agents such as diphenoxylate, loperamide hydrochloride, or codeine can decrease the number of stools, but usually do not affect stool volume. These agents may be particularly effective in patients with rapid intestinal transit, but may consequently have adverse effects on motility in patients with delayed transit by promoting stasis and bacterial overgrowth. Further investigation with controlled studies is required in establishing their benefit in the management of diabetic diarrhea.

Somatostatin and its long-acting synthetic analogue octreotide acetate have been shown to reduce diarrhea in patients with short bowel syndrome, ileostomy, and tumor-induced secretory diarrhea. It has also been shown to be efficacious in many patients with diabetic diarrhea when conventional therapies failed.^{74,75} Physiologically, somatostatin inhibits stimulated water secretion, increases gut absorptive capacity, and suppresses both gastrointestinal hormones that produce diarrhea and counterregulatory hormones that promote hyperglycemia. Octreotide is administered as a subcutaneous injection of 50–75 μg twice daily and may be given with insulin.⁷⁴ The role of newer, long-acting somatostatin analogues remains to be determined. The management of chronic diarrhea in diabetic patients is depicted in Table 52-2.

Celiac Disease

The association of type 1 diabetes mellitus with celiac disease has been reported in both children and adults. The incidence of concomitant disease in children and adolescents is estimated at 4.6%,⁷⁶ and in adults the incidence has been estimated at 1 in 1700. It is unclear whether this rate applies to all racial groups.⁷⁷ Typing of HLA in patients with both celiac disease and diabetes mellitus reveals

TABLE 52-2. Management of Chronic Diarrhea in Diabetic Patients*Concepts*

that the incidence of the histocompatibility antigens HLA-B8, HLA-DR3, and DQW2 are significantly higher in patients with both diseases, and suggests a genetic predisposition to these diseases.^{78,79}

Diabetic diarrhea and celiac disease may have similar clinical manifestations. Certain clues, however, may assist in differentiating the two disease entities. Celiac disease occurs more often in women, and the diarrhea often precedes clinical diabetes. Celiac patients often have evidence of malabsorption, weight loss, peripheral edema, and bone pain, and peripheral neuropathy is often absent. An important clue that the diarrhea in a diabetic patient may be due to celiac disease is a history of repeated episodes of hypoglycemia when the diarrhea is troublesome.

The diagnosis of celiac disease is made by demonstrating the characteristic pathology on jejunal biopsy, which typically shows villous atrophy with crypt hyperplasia. In addition, a clinical and histologic response to a gluten-free diet is required to make the diagnosis. Antiendomysial antibodies more than antigliadin antibody determination has been shown to have high levels of sensitivity and specificity in the screening and follow-up of celiac disease. Treatment consists of removal of gluten from the diet and correcting any deficiencies caused by the absorptive defects.

LARGE INTESTINE

Constipation is seen in up to 60% of diabetic patients who have neuropathies.⁸ This probably represents an increase in frequency above that seen in the nondiabetic population, even though constipation is a common complaint in the general population. With progressive obstipation and constipation, on occasion a massive amount of fecal material may be found in a large atonic dilated colon and may simulate intestinal obstruction with fecal impaction. This may lead to stercoral ulcerations, the result of subsequent mucosal erosion by feces in the rectum. A study of colonic motility in patients with diabetes mellitus revealed abnormalities related to feeding in the myoelectrical and motor responses of the colon that correlated closely with symptoms of constipation.⁸⁰⁻⁸² The most consistent abnormality is the absence of the normal rapid increase in colonic spike motor activity within the first 30-minute postprandial period. The colon was found to respond to drugs that stimulate colonic motility, for example, metoclopramide or neostigmine, suggesting that neural control mechanisms were abnormal while colonic muscular activity remained intact.⁸²

Like other intestinal motor abnormalities, large bowel motility problems are usually seen in patients with DAN. Treatment is

symptomatic, initially with the use of increased dietary fiber, and regular use of laxatives or stool softeners. Unresponsive patients may benefit from drugs that act at the myoneural junction or directly on the smooth muscle, for example, metoclopramide.⁸⁰⁻⁸² Impaired anorectal function determined by anorectal manometry occurs in the diabetic population.⁸³

Its association with DAN is supported by the finding of an abnormal anorectal reflex in 3 of 11 diabetic patients with DAN and in none of 9 diabetics without DAN. Decreased rectal sensation and impaired function of the external and internal sphincters have been suggested as causes of fecal incontinence in diabetics.⁷³ Biofeedback is performed by inserting a balloon in the external canal and having the patient squeeze, while allowing the patient to visualize and note the increased balloon pressure on a viewing device. It has been utilized in an effort to lower the threshold of conscious rectal sensation. Good to excellent results, characterized by a 75% or greater reduction in the frequency of soiling episodes, has been reported in 70% of diabetic patients.⁷³ Incontinence frequently coincides with the onset of diabetic diarrhea and may simply respond to antidiarrheal therapy. According to two recent studies, diabetes mellitus may be associated with an increased risk of colorectal cancer in both men and women after adjusting for other risk factors.^{84,85} Thus one cannot assume that a change in bowel habits is related to the diabetes, and therefore such changes require an appropriate evaluation.

BILIARY TRACT

Cholecystopathy

A common feature in diabetic patients is the presence of an enlarged gallbladder, which may increase to three times the normal size. Diabetic neurogenic gallbladder has been characterized using ultrasonography and scintigraphy imaging techniques that evaluate gallbladder motility, and these studies have shown impaired gallbladder contractility and emptying.⁸⁶⁻⁹¹

Eating normally stimulates gallbladder contraction by the mechanisms of (1) cephalic vagal stimulation, (2) mechanical gastrointestinal distension stimulating cholinergic reflexes, and (3) chemical interaction of food and digestive products, causing the release of a complex array of hormones, especially cholecystokinin (CCK), which can modulate gallbladder motor function. DAN, a frequent complication of longstanding diabetes, impairs parasympathetic (vagal) regulation in the gut and other organs. Therefore it is not unexpected that patients with DAN have impaired gallbladder motility that may relate to the severity of the neuropathy.^{87,92}

However, other factors may have a pathophysiologic role. Stone and collaborators demonstrated a decreased gallbladder emptying rate in patients with DAN in response to CCK. They postulated that the gallbladder smooth muscle in diabetic patients with autonomic neuropathy may be less sensitive to hormonal stimulation.⁹¹ Mitsukawa and coworkers reported elevated levels of CCK in diabetic patients with DAN compared with controls after ingesting egg yolk,⁸⁷ a known stimulant of CCK release. This occurred despite impaired gallbladder emptying in these diabetic patients, and decreased responsiveness of the gallbladder wall to CCK was again proposed. More recently, however, Fiorucci and associates studied gallbladder contractility in response to either a meal or separate cephalic or hormonal stimulation.⁹³ They found that gallbladder emptying induced by an ordinary meal was comparable in

diabetic patients and healthy controls, and were unable to confirm any differences in gallbladder emptying induced by hormonal stimulation with CCK/erulein. They demonstrated that gallbladder emptying in response to cephalic stimulation is abolished in diabetic patients with DAN, which paralleled reductions of gastric acid secretion and pancreatic polypeptide release induced by vagal stimulation. These functional abnormalities are analogous to vagotomy and atropine infusion, which may impair normal gallbladder contractions in response to a meal. Erythromycin may be effective in reducing gallbladder volume in diabetic patients.^{94,95} However, treatment with metoclopramide does not improve gallbladder emptying.⁸⁰ Obesity has been associated with an increased incidence of gallstones and may also reduce gallbladder emptying in healthy subjects. However, a recent study contradicted these earlier studies and found no correlation between weight and delayed gallbladder emptying in both healthy and diabetic subjects.⁹¹ This study also demonstrated that the type of treatment of the diabetics, the presence or absence of peripheral neuropathy, and the degree of diabetic control do not appear to be independent risk factors for impaired gallbladder contractility in diabetic patients.⁹¹ Further work is needed to understand these discrepancies.

Cholelithiasis

The presence of diabetes is often mentioned as an independent risk factor for the development of cholelithiasis, along with female gender, obesity, advancing age, and multiparity.⁹⁶ Several autopsy studies have reported a higher frequency of cholelithiasis in diabetic individuals than in the general population (30.2% in diabetic patients compared with 11.6% in nondiabetic patients),^{97,98} although other reported series were not confirmatory.^{99,100} One survey of 641 patients in a health maintenance organization found the incidence of diabetes to be nearly 30% in those with asymptomatic cholelithiasis.¹⁰¹ However, this observation was not corroborated in several subsequent population-based studies,^{102–105} and comorbid conditions including type IV hyperlipidemia and obesity, also risk factors for gallstone formation, may confound the effect of diabetes.^{103–108}

The pathogenic mechanism for the proposed increased risk of cholelithiasis in diabetes is believed to involve incomplete gallbladder emptying secondary to the diabetic neurogenic gallbladder as well as supersaturated bile and hyperinsulinemia. One study of type 2 diabetic patients revealed an increase in bile supersaturated with cholesterol and reduced bile acid concentration, which perhaps predisposed these patients to cholesterol precipitation and stone formation.¹⁰⁹ However, patients with type 1 diabetes had normal bile composition. Meinders and colleagues compared bile cholesterol saturation and bile acid composition in 12 nonobese, male type 1 diabetic patients and 28 normal healthy controls, and found that the total bile lipid concentration in the bile-rich duodenal aspirates examined were actually lower in this diabetic population.¹¹⁰

Hyperinsulinemia, which is frequently present with type 2 diabetes, may be a factor in gallstone formation.¹¹¹ Insulin itself stimulates the enzyme hepatic hydroxymethyl glutamyl co-enzyme A reductase, which is the rate-limiting step in hepatic cholesterol biosynthesis. A case-control study demonstrated significantly higher fasting plasma insulin levels in diabetic patients with gallstones than in diabetic patients without gallstones.¹¹² Also, insulin therapy may increase bile lithogenicity. Studies in Pima Indians have shown that improved glycemic control with insulin therapy results in a contracted bile acid pool and increased cholesterol saturation index from 114–181%.¹¹³

The management of asymptomatic gallstones is an evolving issue. Until the 1980s, prophylactic cholecystectomy was recommended in all operable patients in the general population with gallstones because of the perceived risk of potential gallstone complications. However, several recent studies have established that asymptomatic gallstones rarely lead to life-threatening complications, and therefore the risk and expense of surgery outweigh the benefit.^{101,114–116} Whether this applies specifically to the diabetic population has been debated. A few questions have been answered and many still remain. The course of treatment for diabetic patients with asymptomatic gallstones requires further examination of these questions.

First we need to know if diabetic patients with silent gallstones are more likely to develop complications. The natural history of cholelithiasis in diabetes is largely unknown because no prospective cohort studies have been undertaken. However, McSherry and associates followed a group of 135 patients, of whom 30% had diabetes with asymptomatic cholelithiasis for 5 years.¹⁰¹ Outcome data were not broken down; however, the outcome in the diabetic groups appeared to be no different than others in the study. Only 1 patient developed symptoms during their follow-up period and 1 required surgery (mean of 47 months) after diagnosis. Other studies have demonstrated that asymptomatic patients or patients with nonspecific symptoms (e.g., nausea) have a favorable prognosis in their natural history, and were unable to show whether the fate of persons with diabetes is different. Thus it seems that asymptomatic patients with diabetes mellitus are no more likely to develop symptoms than the general population.

Uncertainty remains as to whether diabetic patients with silent gallstones develop complications more frequently; interestingly the complications that arise are probably more severe than those in nondiabetic patients. As one author states, "it is true that when the silent gallstone speaks in the diabetic, it is usually with a loud, vicious roar."¹¹⁶ Rabinowitch first suggested that diabetic patients who develop cholecystitis do worse than nondiabetic patients because of the high risk of infection-related complications of cholelithiasis.¹¹⁷ Indeed, diabetic patients have a higher susceptibility to infection, secondary to defects in host-defense mechanisms, including abnormal neutrophil chemotaxis, phagocytosis and bactericidal activity, as well as depressed cell-mediated immunity. Earlier studies reported a 22% incidence of severe gallbladder disease (hydrops, perforation, and empyema),¹¹⁸ and others concurred, noting a 20–40% rate of advanced inflammation among diabetic patients presenting with acute cholecystitis.^{119–121} One review of patients with perforation complicating acute cholecystitis found that 16–25% of the subjects had diabetes.¹²² Older age and presence of atherosclerosis were risk factors for perforation. Also emphysematous cholecystitis is more common in diabetes, and occurs in up to one-third of reported cases. The course of this form of acute cholecystitis is more severe and has been associated with a 30-fold increase of gangrene and a threefold increase of both perforation and death.¹²² The gas-forming organisms implicated in its pathogenesis include *Clostridium welchii*, which is cultured most often, as well as anaerobic streptococci, *Escherichia coli*, *Staphylococcus aureus*, *Pseudomonas*, and *Klebsiella*.

In the past, diabetic patients with silent gallstones were advised to have cholecystectomy because of the belief that infectious and inflammatory complications were more likely to develop, with subsequent higher morbidity and mortality rates. In the 1960s two reports supported this suspicion. Turill and collaborators, at Los Angeles County Hospital, found the mortality rate to be fivefold

higher in diabetic than in nondiabetic patients, with deaths occurring almost exclusively in patients admitted with complicated cholelithiasis undergoing emergent surgery.¹²³ Advancing age was also a factor because diabetic patients in their fifth and sixth decades of life, undergoing emergency surgery for complicated cholelithiasis, had a 20-fold greater mortality than for nondiabetic patients. In 1962, Mundth compared diabetic and nondiabetic patients operated on for gallstones over a 15-year period¹²⁴ and found higher mortality and morbidity in diabetic patients operated on for complicated cholelithiasis, but not in those undergoing elective surgery. Thus oral cholecystography was performed in diabetic patients as a screening measure for gallstones, and early prophylactic cholecystectomy was then performed in all diabetic patients having no surgical contraindications.

The existence of comorbid conditions rather than diabetes as a single risk factor may be a more important predictor of outcome. Haff and coworkers studied 1000 consecutive patients who underwent biliary tract surgery to identify factors that influenced morbidity.¹²⁵ Diabetic patients had more complications than nondiabetic patients, but these differences vanished when the data were corrected for the presence of cardiovascular disease and other associated illnesses. Later, Walsh and associates demonstrated that rates of death among diabetic patients and nondiabetic patients undergoing biliary tract surgery were nearly identical.¹²⁶ The authors attributed this to advances in antibiotic therapy and postoperative hemodynamic monitoring. The presence of renal and vascular occlusive disease were the two major determinants of postoperative morbidity. In 1988, however, Hickman and colleagues studied the influence of diabetes on morbidity and mortality of patients undergoing surgery for acute cholecystitis, and found that infectious complications occurred threefold more often in diabetic patients than in nondiabetic controls, and all deaths (4.2%) occurred in diabetic patients as a result of sepsis.¹²⁷ Concurrent medical disease was more common in diabetic patients than in nondiabetic patients, but did not account for all of the increased morbidity. Ransohoff and associates reviewed the course of acute cholecystitis between 1960 and 1981 in 311 patients.¹²⁸ Death occurred in 3 of 46 patients with diabetes and 1 of 263 without diabetes. The difference was not statistically significant. In contrast, patients in this study who had azotemia were found to have a markedly higher mortality rate compared with patients without azotemia (27% compared with 2%).¹²⁸ These data support the importance of comorbid diseases and imply that complications of renal or vascular disease are more important in escalating the risk of morbidity and mortality in patients with biliary tract disease than is diabetes alone.

Friedman and coworkers used decision analysis to assess whether diabetic patients with asymptomatic gallstones should have expectant management or prophylactic cholecystectomy.¹³⁰ Three variables were studied as to their influence on the optimal choice of therapy: the rate at which diabetic patients develop symptoms, the probability of requiring emergency surgery once symptomatic, and the mortality rate during emergency surgery. Their conclusion favored expectant management over prophylactic cholecystectomy in diabetic patients with asymptomatic gallstones.¹²⁹ However, estimates of these variables in some cases were only educated guesses since true data on the natural history of diabetic patients with gallstones are scarce.

Laparoscopic cholecystectomy has now become the procedure of choice as it shortens hospital stay and may reduce the cost of surgery. Less than 5% of patients will require conversion to the standard open cholecystectomy for technical reasons.¹³⁰ The mor-

tality associated with laparoscopic cholecystectomy in the 1990s (0–0.1%) was less than the mortality associated with open cholecystectomy (0.17–1.80%) in the 1980s. The incidence of common duct injury associated with laparoscopic cholecystectomy was higher in the 1990s than in the 1980s, when open cholecystectomy was widely used.^{131–135} As surgeons become more experienced with laparoscopy, the morbidity associated with the procedure should decrease.

Other therapeutic options are available for patients who are poor operative candidates or who refuse surgery. These include dissolution therapy with oral bile salts or extracorporeal shock-wave lithotripsy. Only a small subset of patients with symptomatic gallstones are appropriate candidates for these therapies. Candidates for treatment with bile salts include those with noncalcified cholesterol gallstones and a patent cystic duct. The composition of stones can be determined indirectly by oral cholecystography or ultrasound. Small stones that appear to float on an oral cholecystograph are mostly cholesterol, and are more likely to dissolve with oral therapy. Success rates for stone dissolution are about 60% for those patients who meet optimal criteria. However, successful dissolution of 30% is more typical, and gallstones frequently recur after bile salt therapy is stopped.¹³⁶ In one study of 40 patients who were followed to complete dissolution of their gallstones, 43% had stone recurrence after 4 years, but only 49% had recurrence when observed after 11 years.¹³⁷

Extracorporeal biliary lithotripsy uses high-amplitude sound waves that can fragment gallstones but pass through most soft tissue without harm. A functioning gallbladder is essential to allow emptying of the fragments into the common bile duct and subsequently into the small intestine. Success rates for this therapy depend on (1) stone characteristics of size, number, and composition; (2) energy and number of shock waves administered; (3) use of adjuvant bile acid therapy; and (4) gallbladder emptying.¹³⁸

LIVER

Diabetes Mellitus and Liver Disease

Glycogen-Laden Hepatomegaly

Diabetes mellitus is associated with an increased frequency and variety of hepatic histopathologic lesions. A common lesion is an increase in liver glycogen demonstrated both at autopsy and in biopsy material (Fig. 52-3). This accumulation of glycogen produces a clear appearance in the cytoplasm and vacuolization of the hepatocyte nuclei.¹³⁹ It has been reported in up to 80% of both type 1 and type 2 diabetic patients. Increased glycogen infiltration appears to be associated with treatment with large amounts of insulin, particularly in young, brittle diabetic patients. This process resolves with reduction of insulin levels.¹⁴⁰

Fatty Liver

The accumulation of triglycerides in the liver of diabetic patients may result in steatosis. Fatty liver is especially prevalent in patients with type 2 diabetes, particularly in the presence of obesity. Approximately 50% of obese type 2 diabetics will have biopsy-proven excess fat in their liver.¹⁴¹ In T1DM, fatty liver is usually found in the setting of inadequate diabetic control¹⁴² and is one-tenth as frequent as in T2DM. The pathophysiologic basis for the development of diabetic fatty liver is poorly understood. Accumulation of fat as intracellular lipid occurs because the rate of

FIGURE 52-3. Liver biopsy in a type 2 diabetic patient demonstrating glycogen deposition (white arrow) and fatty metamorphosis (steatosis) (black arrow).

triglyceride synthesis exceeds the liver's capacity to secrete newly formed triglyceride as very low density lipoprotein (VLDL).¹⁴⁰

In T1DM, fat deposition may result from insulin deficiency and hyperglycemia, both of which enhance the release of free fatty acids from adipose tissue. This provides substrate for hepatic triglyceride synthesis. In addition, low insulin levels may lead to reduced triglyceride secretion by the liver.

In T2DM, fatty liver appears to be a manifestation of obesity and insulin resistance rather than hyperglycemia and insulin deficiency. The greater dietary intake of fats and carbohydrates and portal hyperinsulinemia lead to increased synthesis of hepatic triglycerides at a rate that exceeds the liver's capacity to secrete newly formed VLDL. Reducing caloric intake or dietary intake of carbohydrates can reverse the fat deposition.^{140,143}

Clinically, steatosis in diabetic patients leads to hepatomegaly, and occasionally tenderness to palpation in T1DM. Liver biochemistries are often normal or minimally elevated. Findings on liver biopsy include large cytoplasmic fat globules that displace the cell nucleus by light microscopy and abnormal mitochondria and displacement of organelles by fat globules on electron microscopy.

A controversial issue has been whether associated obesity rather than diabetes accounts for the fatty infiltration. Observations support the former because (1) similar hepatic histologic changes are seen in nondiabetic obese patients, (2) fatty liver is ten times more frequent in T2DM, where obesity is common, and (3) steatosis in diabetic patients may regress with weight reduction.¹⁴⁴⁻¹⁴⁷

Cirrhosis

Diabetes mellitus is also associated with cirrhosis of the liver. Recent data suggest that steatosis alone can progress directly to cirrhosis. Diabetic patients with steatosis may have intracytoplasmic hyaline and centrilobular fibrosis by light microscopy, and collagen bundles lining the space of Disse by electron microscopy.¹⁴⁸ These changes may represent the initial fibrotic steps leading to a cir-

rotic liver. A recent study found that T2DM was significant more common in cryptogenic cirrhotic patients and nonalcoholic steatohepatitis (NASH) patients than cirrhotic patients with primary biliary cirrhosis (PBC) or hepatitis C. The authors suggest that NASH may be a cause of cryptogenic cirrhosis. A recent study published by the Mayo Clinic found that older age, obesity, diabetes mellitus, and an AST:ALT ratio greater than 1 were good predictors of significant liver fibrosis (bridging/cirrhosis) in patients with NASH.¹⁴⁹

Conversely, established liver disease from any cause may lead to glucose intolerance. Carbohydrate intolerance is seen in approximately 50% of patients with liver disease and 80% of patients with cirrhosis.¹¹¹ This is suggested to be secondary to impaired binding and degradation of insulin by the liver due to a reduced first-pass effect.¹¹⁰ However, glucose intolerance also occurs in cases of liver disease with low insulin levels. The carbohydrate intolerance is most likely due to a multitude of biochemical and physiologic arrangements that accompany liver disease, including portosystemic shunting of glucose, elevated glucagon¹⁵⁰⁻¹⁵³ and growth hormone¹⁵⁴ levels, peripheral and hepatic resistance to insulin, malnutrition, elevated levels of free fatty acids, and hypokalemia.¹¹⁵

Hepatitis

A diabetic patient is at increased risk for developing viral hepatitis (B and C) with a rate 2-4 times that of a control population.¹⁵⁵ One study demonstrated an increased HBsAg in diabetic subjects compared with age- and sex-matched controls.¹⁵⁶ Like factors include frequent hospital exposures¹⁵⁶ and perhaps an increased susceptibility to infection. Previously, the high incidence of hepatitis in diabetes was attributed to frequent needle sticks, with the advent of sterile disposable syringes, this no longer remains a valid postulate. Furthermore, several retrospective studies have shown a stronger association between hepatitis C infect

and diabetes mellitus when compared with other types of hepatitis.¹⁵⁷⁻¹⁶⁰ About 20% of patients with hepatitis C cirrhosis have diabetes mellitus, compared with only about 9% of patients with hepatitis B cirrhosis.¹⁵⁸ Others, however, have not found this association between hepatitis C infection and diabetes [AQ 14]mellitus.¹⁶¹ Alfa-interferon therapy should be administered with caution in patients with diabetes mellitus. It has been reported that 10% of patients with hepatitis developed insulin autoantibodies after 6 weeks of therapy with INF α .¹⁶² On the other hand, two large studies that examined the adverse effects of INF α in patients with chronic viral hepatitis found that less than 1% develop clinical diabetes mellitus.¹⁶³⁻¹⁶⁵ A recent study observed improved glucose tolerance in patients with chronic hepatitis treated with INF α , regardless of whether they had a previous history of diabetes or not.¹⁶⁴

The treatment of diabetic patients with oral hypoglycemic agents also may increase the risk of hepatic dysfunction. The sulfonylureas (chlorpropamide, tolazide, tolbutamide, and acetohexamide) have each rarely been associated with jaundice. The highest reported incidence occurs with chlorpropamide, at a rate of 0.5–1.0%.¹⁶⁶ The toxic effect is usually cholestasis, but hepatocellular injury or a mixed picture are occasionally seen.¹⁶⁶ Less frequently, hepatocellular necrosis can occur secondary to a hypersensitivity reaction to the central sulfonyl group, which acts as the antigenic stimulus. Rarely, the formation of granulomatous liver disease has been attributed to these agents.¹⁶⁷

Hemochromatosis

The association between hemochromatosis and diabetes mellitus was first clinically recognized by Trosier in 1871,¹⁶⁸ and later the term “bronze diabetes” was coined by Hanot and Schachmann.¹⁶⁹ This disorder of iron metabolism has a high incidence of concomitant diabetes, with a rate of 75%, according to Saudek¹⁷⁰ (rates in other series range from 14–91%). Different pathogenetic mechanisms have been proposed, and two deserve particular attention.¹⁷¹

Theoretically, extensive iron deposits in the pancreas can result in diabetes. Support rests on pathologic changes in the pancreas with extensive hemosiderin deposits in nearly all cases in which hepatic iron deposition is also noted.¹⁷¹ In addition, other secondary causes of iron overload such as thalassemia and excessive blood transfusions are associated with glucose intolerance or diabetes.¹⁷⁰⁻¹⁷² Third, the glucose intolerance observed with hemochromatosis may improve with phlebotomy.¹⁷³ However, it is likely that the development of diabetes is not solely due to pancreatic damage, because other forms of liver disease and cirrhosis are associated with glucose intolerance. Moreover, secondary causes of iron overload have been reported to produce insulin resistance that has been attributed to iron deposition in peripheral tissues. Data suggest that the carbohydrate intolerance results from a combination of iron overload in the liver and pancreas.

It has also been suggested that the association between diabetes mellitus and hemochromatosis is that they are genetically linked or that subclinical diabetes is exaggerated by hemochromatosis. This was first suggested by Balcerzak and coworkers, who studied five separate families with hemochromatosis.¹⁷⁴ Oral glucose tolerance, quantification of iron stores, and measurement of insulin levels was performed in 30 relatives of each of the five cases. They concluded that the association between these diseases was not due to iron overload, based on these observations: (1) dia-

betes mellitus occurred in 47% of family members with normal iron stores, (2) there was poor correlation between the amount of iron deposition and the presence of diabetes, (3) glucose intolerance appeared in family members despite adequate therapy for the hemochromatosis.^{140,174} No correlation with HLA haplotypes between these diseases has been found.¹⁴⁰ However, some studies have shown a higher prevalence of the C282Y mutation of the hemochromatosis gene in patients with T2DM.

PANCREAS

Abnormalities of pancreatic exocrine secretion are seen commonly in diabetic patients. The abnormalities of secretion include decreased volume and amylase content, and at times reduced bicarbonate content. These abnormalities, which are usually not clinically apparent, may be due to vagal neuropathy, deficient stimulation by insulin, or inhibition by glucagon. Although patients with diabetes mellitus frequently have a 50–60% reduction in bicarbonate and enzyme secretion, this deficiency does not result in steatorrhea, nor is it likely to play a role in diabetic diarrhea.¹⁷⁵

Acute Pancreatitis

Individuals with diabetes are at increased risk for acute pancreatitis. The damage appears to result from hypertriglyceridemia and/or vascular lesions in the diabetic pancreas. Acute pancreatitis may be lethal if it is associated with diabetic ketoacidosis because of a predisposition to hypovolemic shock.¹⁷⁶

Acute pancreatitis in nondiabetic individuals often results in transient hyperglycemia and may induce glucose intolerance. Only rarely is there a progression to permanent diabetes. However, 21–26% of patients with acute necrotizing pancreatitis subsequently develop diabetes,¹⁷⁷ and 66–100% of those who undergo partial pancreatectomy develop diabetes. Hyperamylasemia occurs in up to 80% of patients with diabetic ketoacidosis. Its origin is purely pancreatic in only half of the cases and there is no correlation between the presence, degree, or type of amylase and gastrointestinal symptoms that occur with diabetic ketoacidosis.¹⁷⁸ Acidosis from any cause may result in nonpancreatic amylase elevation.

Chronic Pancreatitis

Pancreatic exocrine function is diminished in a high percentage of patients with diabetes mellitus, especially in patients with T1DM.¹⁷⁹ In addition, low levels of pancreatic lipase and immunoreactive trypsin have been found in T1DM.¹⁸⁰ Nakanishi and associates compared pancreatic duct morphology via endoscopic retrograde pancreatography in 43 patients with T1DM to that in 334 patients with T2DM.¹⁸¹ They found that 40% of type 1 and 26% of type 2 diabetic patients had abnormal pancreatograms. A particularly high prevalence of ductal abnormalities was found in those who had slowly progressive T1DM. Pancreatic histopathologic analysis in patients with T1DM showed atrophy of exocrine pancreatic cells and infiltration with CD8 T lymphocytes.¹⁸¹ In summary, there is increasing evidence of both structural and functional pancreatic exocrine abnormalities in T1DM.

The causes of pancreatic exocrine dysfunction in diabetes remain unknown. It has been postulated that the absence of the local trophic effects of insulin may cause this phenomenon. Diabetic mi-

croangiopathy could be a causative factor in diabetic pancreatic exocrine dysfunction, but investigations have found no correlation between pancreatic ductal changes and the extent of vascular abnormalities.¹⁸¹ Interestingly, patients with diabetes may have autoantibodies to pancreatic cytokeratin, which is found in both the exocrine and endocrine pancreas, suggesting a possible immunologic pathogenesis.¹⁸¹

Conversely, chronic pancreatitis frequently results in glucose intolerance or overt diabetes. In Western societies, alcoholic chronic pancreatitis accounts for 0.5% of all diabetes. This results in sclerosis of the pancreatic islets and impaired insulin secretory response.¹⁸² The typical patient with pancreatic diabetes gives a history of alcohol overindulgence for 5–15 years, followed by recurrent episodes of abdominal pain, and then by the appearance of diabetes, steatorrhea, or both, generally 1–20 years later. Patients with diabetes secondary to chronic pancreatitis often are very sensitive to insulin and therefore may be more susceptible to severe hypoglycemia.¹⁸³ Higher caloric intake is generally required because of the frequent finding of weight loss, due to malabsorption from associated pancreatic exocrine insufficiency. Therapeutically, these patients generally require pancreatic enzyme replacement as well.

Cystic Fibrosis

Cystic fibrosis is an autosomal recessive disorder that is linked to a gene found on chromosome 7.¹⁸⁴ Moderate to severe glucose intolerance occurs in approximately 40–50% of patients with cystic fibrosis, and virtually all cystic fibrosis patients have a diminished insulin secretory response.¹⁸⁵ The glucose intolerance appears to be a consequence of anatomic disorganization of the islets of Langerhans produced by pancreatic fibrosis. Additionally, studies have shown that patients with diabetes secondary to cystic fibrosis have predominantly pancreatic fibrosis as opposed to the replacement with adipose tissue seen in nondiabetic cystic fibrosis.¹⁸⁶

Pancreatic Carcinoma

There appears to be an increased association between diabetes mellitus and carcinoma of the pancreas. It is not clear whether there is an increased risk of pancreatic carcinoma in patients with diabetes or whether the early diabetic manifestations are the result of an undiagnosed pancreatic tumor. Ishikawa and coworkers found a significantly higher incidence of hyperplastic and well-differentiated neoplastic changes of the pancreatic duct in patients with diabetes for greater than 2 years, and suggested that diabetes mellitus could be a cofactor for pancreatic carcinogenesis.¹⁸⁶ A recent Italian study found that of 720 patients with pancreatic cancer, 22% had diabetes, compared with only 8% of 720 matched controls.¹⁸⁷ However, when only patients with diabetes of 3 or more years' duration were considered, there was no significant difference between the groups. The study concludes that diabetes is not a risk factor for pancreatic cancer. A clue to the diagnoses of pancreatic carcinoma in a diabetic patient is the onset of weight loss and deterioration of glycemic control. Carbohydrate intolerance may manifest before the emergence of symptoms of pancreatic malignancy. Therefore pancreatic malignancy should be considered when poorly controlled diabetes develops in a thin, middle-aged, or elderly individual, particularly in the absence of a family history of diabetes, regardless of whether unexplained systemic symptoms coexist.

SUMMARY

This chapter has reviewed the relationships between diabetes mellitus and the gastrointestinal system. The protean manifestations of diabetes often eventuate in gastrointestinal problems, principally as a consequence of autonomic visceral neuropathy. The mechanisms, clinical presentations, and treatment strategies for each of these have been explored. In addition, those disorders of the gastrointestinal system that have a special relationship with diabetes were discussed. The physiologic and possible pathophysiologic relationships between gastrointestinal hormones and islet cell function are explored in Chaps. 4 and 6.

Diabetes and the Skin

John Olerud

The skin is the largest organ of the body, and it is readily available for inspection and scientific study. Small wonder there have been so many clinical and scientific studies related to the skin in patients with diabetes. The skin is affected in one way or another in essentially 100% of diabetic patients. Dysregulation of glucose, insulin, and lipids leads directly to physical signs in the skin of patients with diabetes.

Chronically elevated blood sugar results in nonenzymatic glycosylation (NEG) of cutaneous proteins, which eventually leads to irreversible advanced glycation end-products (AGEs; see Chap. 13).¹ AGEs have been proposed as the mechanism for clinical phenomena such as thickened skin and scleroderma-like changes seen in patients with diabetes,² as well as limited joint mobility (LJM).³ Structural proteins, such as collagen, that have undergone NEG become insoluble and resistant to degradation.¹ Certain AGEs are clearly related to glycemic control, whereas others change with age as well as with glycemic control.^{1,4,5} It is encouraging to note that intensive insulin therapy for patients in the Diabetes Control and Complication Trial (DCCT) resulted in lower levels of skin collagen AGEs in parallel with reduction in HbA_{1c}, as well as with reduction in the risk of retinopathy, nephropathy, and neuropathy.⁶

Normal activities of insulin and lipoprotein lipase are necessary for normal production and catabolism of certain plasma lipids, particularly very-low-density lipoproteins (VLDLs). Diabetes is the most common cause of severe hypertriglyceridemia⁷ (see Chap. 47). Some individuals with insulin resistance and insufficient levels of insulin have high levels of serum triglycerides with cutaneous xanthomas, particularly the clinical variant known as eruptive xanthomas. On the other hand, individuals with insulin resistance and hyperinsulinemia may have the clinical manifestations of acanthosis nigricans.

In addition to these biochemical and endocrine influences on the skin, there are profound changes in cutaneous structure and function in diabetes based on abnormalities of nerves and blood vessels. Structural studies document that cutaneous sensory innervation is diminished in patients with diabetes compared with controls and even further diminished in diabetic patients with measurable neuropathy.⁸ The most striking reduction in sensory innervation occurs in the epidermis.⁹ These observations have been documented by functional studies as well.¹⁰ There is a growing body of evidence that nerves and neuropeptides may be important for normal immune function¹¹ as well as for normal tissue repair.¹²⁻¹⁴ Poor tissue repair and infections are contributing factors to skin ulcers. It has been documented that nonhealing ulcers are the most frequent proximal cause of amputation, which, as one would predict, is more common in patients with diabetic neuropathy.^{15,16}

The cutaneous microvasculature likewise shows both structural and functional abnormalities and contributes to development of lower extremity ulcers. Structural abnormalities of blood vessels include (1) an increase in the overall thickness of the walls of the microvessels,¹⁷ (2) an increased number of gaps between endothelial cells and pericytes in postcapillary venules,¹⁸ (3) homogeneous basement membrane thickening (BMT) between endothelial cells and pericytes of dermal microvessels,^{18,19} and (4) an increase in size and number of the periadventitial fibroblast-like cells (veil cells).²⁰

Functional abnormalities of the diabetic microvasculature include (1) increased permeability,²¹ increased baseline capillary pressure,²² and decreased capillary peak blood flow following arterial occlusion²³; (2) a normal resting blood flow to capillaries in dorsal fingers and toes, but a decreased response to heat-induced hyperemia²⁴; and (3) an increased resting cutaneous blood flow in the legs and feet of diabetic patients with neuropathy, but a deficiency in the normal hyperemic response to heating.^{25,26} The defective hyperemic response was greater on the legs than arms and correlated with duration of diabetes, retinopathy, and proteinuria.²⁶ Taken together, the observations regarding functional changes of the microvasculature in diabetes show the vessels to be "leakier," less constricted by the sympathetic nervous system at baseline, and less able to respond maximally to thermal and hypoxemic stress. The lower extremities generally are more affected than upper extremities.

In this chapter, we review the current literature regarding conditions that appear to be directly linked to the endocrine, vascular, neurologic, and immunologic impairment seen in diabetes mellitus (DM). These conditions include ulcers, acanthosis nigricans, diabetic thick skin, cutaneous infections, and cutaneous xanthomas. A number of other clinical conditions associated with diabetes will be reviewed, although the pathobiology of the disorders remains unclear. These include necrobiosis lipoidica, granuloma annulare, diabetic dermopathy, bullosis diabeticorum, and acquired perforating dermatosis. Glucagonoma and complications of insulin injection are reviewed as well because of their special importance in the management of diabetic patients.

DIABETIC ULCERS

Without question, the most important skin lesions in diabetic patients are lower extremity ulcers. Lower extremity ulcers cost the Medicare system \$1.5 billion in 1995 (see Chap. 51).²⁷ Pecoraro and coworkers noted that ulcers were the proximal cause of amputation in 67 of 80 (84%) diabetic patients hospitalized for amputation.¹⁵

The annual incidence of foot ulcers was nearly 2% in a retrospective cohort study of 8905 patients with diabetes in a health maintenance organization.²⁸ It has been estimated that 15–24% of diabetic patients with foot ulcers will eventually undergo amputation.²⁹ A publication by the Centers for Disease Control (CDC) suggests that the vast majority (up to 85%) of lower extremity amputations are preventable.²⁹ Despite efforts directed at prevention, the rate of amputation in patients with DM continues to rise.²⁹ This poor result is related in part to the underuse of recommended preventive care practices among patients with DM.³⁰

The etiology of diabetic ulcers is multifactorial.³¹ In a study by Reiber and colleagues,³¹ neuropathy, minor foot trauma, and foot deformity were the commonest causal pathways for lower extremity ulceration, but edema, ischemia, and callus formation were also important contributors. In addition, factors that contribute to lower extremity ulcers in diabetic patients are the same as in patients without diabetes, for example, venous insufficiency, stasis dermatitis, and infection. Occasionally, diabetic patients get ulcerations from conditions associated with diabetes, such as necrobiosis lipoidica and bullosis diabeticorum. When patients with diabetes develop ulcers, healing may be compromised by some of the biochemical, endocrine, neurologic, and microvascular factors discussed above. Nonenzymatic glycosylation (NEG) may affect the function of regulatory or matrix proteins and cells necessary for normal tissue repair.^{32–35}

Vasculopathy is a major factor in the pathogenesis of diabetic ulcers. The greatest risk factor for amputation in a study by Reiber and associates¹⁶ was low cutaneous blood flow as measured by transcutaneous oxygen pressure (TcPO₂). There was a 16-fold excess risk of amputation if the TcPO₂ was below 20 mm Hg. Likewise, when Pecoraro and coworkers assessed risk factors associated with failure of ulcers to heal, they found that the most important predictors of nonhealing were low TcPO₂ and high TcCO₂ in the skin adjacent to the ulcers. In ulcers that healed directly, the mean time to reepithelialization was 89 days despite aggressive outpatient management, including weekly or biweekly visits for debridement by an experienced ulcer care team.³⁶

Sensory neuropathy is also a major factor associated with diabetic ulcers³¹ and lower extremity amputation³⁷ (see Chap. 45). The prevalence of symptomatic sensory neuropathy is 30–40% in diabetic patients compared to about 10% in the nondiabetic population.³⁸ A case-control study by Reiber and collaborators, to assess risk factors for amputation, showed that diabetic patients lacking vibratory sensation had a 15.5-fold excess risk of amputation compared to diabetic patients with intact vibratory sense.¹⁶ Clinical examination and the use of a 5.07 Semmes-Weinstein filament were the most sensitive tests in identifying patients at risk for foot ulceration in a large prospective multicenter trial.³⁹ The combination of neuropathy and limited joint mobility was found to be the most important etiologic factor for foot ulcers occurring on high-pressure (friction) areas of patients with diabetes^{40,41} (Fig. 53-1). It undoubtedly relates to unperceived trauma such as blisters and ingrown toenails, but it may also relate in part to diminished influences of neuropeptides on skin immunity and tissue repair. Ulcers heal very slowly in diabetic patients with neuropathy. Only approximately 31% of 349 patients with diabetic neuropathic foot ulcers receiving standard treatment healed in 20 weeks.⁴²

Management of lower extremity ulcers requires modification of contributing factors. For example, if stasis dermatitis is present, it should be treated with topical steroids on the skin adjacent to the ulcers. Edema control is essential. Peripheral edema was a significant

FIGURE 53-1. Diabetic ulcer on an insensate plantar surface. Debridement was done without anaesthesia.

causal factor in the pathway leading to lower extremity ulceration³¹ and was associated with amputations in 58% of diabetic patients undergoing amputation in a large series from Sweden.⁴³ It has also been shown that TcPO₂ may improve significantly when leg edema is treated.⁴⁴ This may be accomplished by bedrest, leg elevation, sodium restriction, or appropriately used diuretics. Unna boots, ace wraps, compression stockings, and even contact casting may be useful if severe arterial insufficiency does not preclude these interventions. Treatment of underlying local soft tissue infection is important. Approximately 15% of diabetic patients with lower extremity ulcers develop osteomyelitis.²⁸ Osteomyelitis should be suspected in deep or chronically draining ulcers, particularly if bone is exposed. In a study emphasizing decision and cost-effectiveness analysis, it was suggested that diabetic patients with suspected osteomyelitis from a foot ulcer (without systemic toxicity) might receive a 10-week course of culture-guided antibiotics followed by surgical debridement without obtaining noninvasive imaging studies.⁴⁵ Mechanical protection for neuropathic extremities is another key element in therapy of diabetic ulcers. This topic is reviewed in detail in Chap. 51.

Trials of growth-promoting factors and skin equivalents have been under investigation to enhance diabetic ulcer healing.^{46–49} Data on treatment for diabetic ulcers were reviewed at an international Consensus Development Conference on Diabetic Foot Wound Care in Boston, Massachusetts.²⁹ It was concluded that new technologies for the topical treatment of diabetic foot ulcers show “modest benefit” if used with adequate off-loading, debridement, and control of infection. LoGerfo and associates advocate the expanded role of arterial reconstruction for severe diabetic ulceration and gangrene, especially vein bypass grafts to the dorsalis pedis artery (see Chap. 50).⁵⁰ Specialized ulcer care teams in outpatient departments have produced impressive results in the prevention and management of lower extremity ulcers as well as the prevention of amputations.^{51–53} This team approach to ulcer management will become increasingly important as life expectancy for diabetic patients as well as the general population continues to increase.

Without question, the most important ulcer interventions by physicians and other health care professionals are in the area of prevention. These interventions can be summarized as follows:

1. Implement formal outpatient education that includes teaching daily foot inspection, particularly for neuropathic patients.

2. Advise careful selection of footwear that is not rigid or constricting in design or requiring a break-in period. Ill-fitting shoes or socks were the most common reasons for foot ulcers in a study of 314 diabetic patients with ulcers.⁵⁴ Issuing sports shoes to a group of diabetic patients as an experimental variable resulted in a measurable reduction of calluses.⁵⁵ Calluses are a sign of excess friction and are often associated with foot ulcers.
3. Advise patients to inspect shoes for foreign bodies before putting them on and to avoid walking barefoot. Figure 53-2 graphically demonstrates problems that can be encountered by patients with insensate feet walking barefoot.
4. Seek early health care attention for calluses, blisters, ingrown toenails, dermatitis, or athlete's foot.
5. Personally inspect the feet of diabetic patients at each visit.
6. Advise patients with a history of ulceration that they are at high risk for reulceration (34% at 1 year, 61% at 3 years, and 70% at 5 years).⁵⁶ Redouble education and prevention efforts in this group. Lifelong surveillance is required.

ACANTHOSIS NIGRICANS

Acanthosis nigricans (AN) is a skin disorder that in most cases is a marker for hyperinsulinemia and insulin resistance.⁵⁷ The clinical features include a velvety, warty hyperkeratosis, which is black or gray-brown in color, observed on the back and sides of the neck, the axillae, the anogenital region, and other skin folds (Fig. 53-3). The neck is the most consistently affected area⁵⁸ and it is also the most reliable area for quantification of AN.⁵⁹ AN was previously

FIGURE 53-2. A. Nodule on the foot of a diabetic patient with sensory neuropathy. B. X-ray showing a needle in the foot that the patient acquired painlessly while walking barefoot.

A

B

FIGURE 53-3. Acanthosis nigricans on the neck of a black woman with T1DM.

thought to be uncommon or a marker for malignancy, but more recent studies have shown it to be common in certain subpopulations. AN has been observed, for example, with a prevalence of 74% in obese adults,⁶⁰ 66% in primary school children weighing 200% of ideal body weight (IBW), and 27% in children weighing 120% of IBW.⁶¹ An overall prevalence of 7.1% was observed for AN in 1412 unselected primary school children, with 0.5% affected in Caucasian children, 5% in Hispanics, and 13% in African-Americans.⁶¹ These differences among ethnic groups have been emphasized.⁵⁷ In selected subpopulations of Native Americans the prevalence of AN is 40%.⁵⁷ The prevalence of type 2 diabetes mellitus (T2DM) in this subpopulation of Native Americans with AN is 50% in individuals above the age of 40. AN has also been shown to be a risk factor for development of T2DM in a prospective longitudinal study.⁶² AN is strongly correlated with hyperinsulinemia,⁵⁹ and hyperinsulinemia has been demonstrated to be an independent risk factor for the development of ischemic heart disease.⁶³ Some investigators have recommended that AN be used as an inexpensive surrogate marker for hyperinsulinemia to identify children and adolescents with a future risk of T2DM and ischemic cardiovascular disease.^{58,64}

In conditions of insulin resistance and hyperinsulinemia, excess binding of insulin to insulin-like growth factor (IGF-1) receptors has been proposed as a mechanism for AN as well as for androgen excess.^{60,65,66} It is known that high concentrations of insulin stimulate DNA synthesis and cell proliferation *in vitro* through the IGF-1 receptor in fibroblasts,⁶⁷ and that keratinocytes have IGF-1 receptors as well.⁶⁸ Ovarian cells capable of steroidogenesis have likewise been shown to possess IGF-1 receptors.⁶⁶ Molecular biology has been used to identify a number of specific mutations in the insulin receptor gene in patients with AN and type A insulin resistance.⁶⁹ These patients have both severe insulin resistance and hyperandrogenemia.

Earlier authors have emphasized the relationship between AN and malignancy.⁷⁰ However, the frequency of AN and its lack of specificity for malignancy suggests that when history and physical examination are negative, an extensive cancer work-up is unlikely to be productive. Certain drugs such as nicotinic acid⁷¹ and diethylstilbestrol⁷² have been reported to cause AN as well. Treatment for AN is generally ineffective, although disappearance of AN has been observed in obese individuals with weight reduction to IBW^{58,60,65} and with discontinuation of offending drugs.⁷³

DIABETIC THICK SKIN

In a review of the skin manifestations of diabetes in 1989, Huntley concluded that patients with diabetes generally have thicker skin than their nondiabetic counterparts.⁷⁴ He and Walter subsequently presented ultrasound data comparing patients with diabetes (mean age, 44) with control subjects, showing that the skin on the dorsum of the hands and feet was thicker in the diabetic patients.⁷⁵ Likewise, Collier and colleagues used ultrasound measurements to show that flexor forearm and medial upper arm skin in patients with diabetes (mean age, 25) was thicker than in controls. Diabetic patients with disease duration greater than 10 years and those with LJM of the hand had the greatest mean skin thickness.⁷⁶ Although the contention that patients with diabetes generally have thicker skin has not been shown in an unselected population-based study, two well-characterized syndromes of thick skin in diabetic patients are discussed below.

Scleroderma-Like Syndrome (SLS) and Limited Joint Mobility (LJM)

As reviewed,^{77,78} SLS is typically described in children and young adults with type 1 diabetes mellitus (T1DM) in the context of the "diabetic hand syndrome," limited joint mobility (LJM), or "cheiroarthropathy." Skin and joint findings are observed to coexist in a majority of cases, although each may exist independently. Thickening and induration of the skin on the dorsal fingers may be demonstrated by palpation in 8–50% of children with T1DM.^{79,80} SLS and LJM typically begin on the fifth finger and progress radially, as well as from distal to proximal. With increasing duration of diabetes, the changes may be seen proximal to the metacarpophalangeal joint. Thickening of the skin has been shown to result from accumulation of connective tissue in the deep dermis.²

LJM is thought to result from deposition of connective tissue in the periarticular soft tissues around the joint capsule rather than being the result of a true arthropathy.⁸¹ For study purposes, criteria have been defined for staging the severity of LJM⁷⁹ and quantitating restrictions in motion with a goniometer.⁸² For clinical purposes, however, LJM may be well demonstrated by the "prayer sign"⁷⁹ (Fig. 53-4) or the "table top sign."⁸² These signs demonstrate that when the fingers are spread apart, the palmar surface cannot be entirely flattened.

Approximately 50% of adolescent patients with T1DM for more than 5 years are affected.⁷⁹ Adults with T2DM may be affected as well.⁸³ Brik and coworkers⁷⁷ summarize the literature on 1845 patients with T1DM and show that for all studies cited, a correlation was found between LJM or SLS and duration of DM. In all of five studies in which microvascular complications were examined, LJM or SLS correlated with retinopathy. Though other signs of microvascular complications have been reported to be associated with LJM or SLS,^{77,79,82} retinopathy appears to be the strongest association. In a more recent cross-sectional study, 83 patients with LJM and T2DM were compared with 56 diabetic patients without LJM for evidence of diabetic complications. Patients with LJM were 9.3 times more likely to have proliferative retinopathy, 4 times more likely to have cerebrovascular disease, 3.3 times more likely to have nephropathy, and 3.1 times more likely to have coronary heart disease.⁸⁴ Longitudinal control of diabetes as measured by HbA_{1c} was strongly associated with the presence or absence of LJM.⁸⁵

Although the pathogenesis of this condition is controversial,^{86,87} evidence for the role of nonenzymatic glycosylation (NEG) of connective tissue is becoming stronger.⁸⁸ Advanced gly-

FIGURE 53-4. Prayer sign showing limited joint mobility (LJM) and scleroderma-like (SLS) skin changes. This young woman with T1DM also has severe diabetic retinopathy and nephropathy.

cation end-products (AGEs) extracted from skin correlated significantly with signs of LJM in two studies,^{3,88} but not in a third study.⁸⁹ The most compelling data come from a longitudinal prospective study showing a two- to threefold excess risk of LJM with HbA_{1c} levels above 8% over a 2-year period. For every 1% increase in HbA_{1c} level, there was a 2.5-fold excess risk of LJM.⁸⁵ Evidence is accumulating that intensive insulin therapy may be beneficial in the treatment of LJM and SLS. A study of four patients reported a decrease in skin thickness with tight control of glucose.⁹⁰ Monnier and colleagues⁶ reported intensive insulin therapy in 122 patients in the DCCT resulted in lower levels of skin collagen AGEs. While evidence was not presented in that study regarding SLS and LJM, the reduction in skin AGEs suggests the effect of intensive insulin therapy may be beneficial. Another study of 2 patients showed improvement in LJM over a 10-year period using aldose reductase inhibition.⁹¹ Physical therapy to preserve range of motion should be considered as well.

Scleredema

Scleredema is usually described as a rare complication of diabetes. However, in two studies the prevalence was reported to be 2.5% of 484 diabetic outpatients in a Veteran Administration Medical Center in the United States⁹² and 14% of 100 hospital-based diabetic patients at Kuwait University in Kuwait.⁹³ Scleredema in diabetic

patients is characterized as firm nonpitting edema of the skin, symmetrically distributed over the posterior neck, upper back, and shoulders. Occasionally, the skin thickness can be so severe as to limit complete range of motion of the neck and shoulders (Fig. 53-5). Usually, however, it is asymptomatic, a fact that could lead to considerable underreporting of the phenomenon by both patients and physicians. A population-based study would provide the best data regarding the true prevalence of scleredema of diabetes.

FIGURE 53-5. Top: A man with adult-onset DM with scleredema diabeticorum so severe that it restricts his efforts at neck extension. Bottom: A close-up view of the remarkable thickening of skin on his neck.

A

B

Scleredema of diabetes or scleredema diabeticorum⁹² is often reported as part of the spectrum of scleredema adultorum.⁹⁴ It may be seen in both T1DM and T2DM, but is much more common in type 2 disease.^{92,94} The classical Bushke type of scleredema adultorum occurs after a febrile illness, but more commonly scleredema adultorum occurs without a preceding febrile illness. These types of scleredema are similar to the scleredema of diabetes in clinical appearance except they involve the face more often and may resolve spontaneously within 2 years.⁹⁴ Monoclonal gammopathy and multiple myeloma have been reported with scleredema.⁹⁵ Histopathology shows remarkable thickening of the dermis with acid mucopolysaccharide staining on the majority of biopsies.⁹⁶

The pathogenesis is unclear. Ohta and collaborators⁹⁵ showed that serum from patients with scleredema and a paraproteinemia caused enhanced synthesis of extracellular macromolecules in cultured fibroblasts. No consistent pattern of cellular response was observed, however. One patient reported had diabetes. In another diabetic patient with paraproteinemia a sixfold increase in procollagen synthesis was demonstrated in fibroblasts taken from lesional skin.⁹⁷ These studies focus on the possibility that circulating serum factors may be responsible for this condition. Similar studies on scleredema of diabetes without paraproteinemia would be of interest. Currently there is no established therapy for the scleredema of diabetes, and it usually persists chronically. Case reports regarding the use of electron beam radiation, penicillin, cyclosporine, bath PUVA, and prostaglandin E₁ have recently been referenced.⁹⁸

CUTANEOUS INFECTIONS

Gilgor extensively reviewed cutaneous infections in diabetic patients and concluded that there is little evidence that well-controlled patients with diabetes are more prone to skin infections.⁹⁹ A review of 500 diabetic patients in 1927, before the era of modern metabolic management and antibiotic therapy, contributed to the view that the incidence of furunculosis, carbuncles, erysipelas, and epidermophytosis is increased in diabetic patients.¹⁰⁰ Infection clearly makes diabetes more difficult to manage and, conversely, hyperglycemia and ketoacidosis diminish chemotaxis, phagocytosis, and bactericidal ability of white blood cells. It is difficult, however, to correlate hyperglycemia with skin infections.⁹⁹ While population-based studies of prevalence of cutaneous infections are for the most part lacking, we will discuss some of the cutaneous infections that appear to be overrepresented in diabetic patients. A recent review emphasizes these associations.¹⁰¹

Bacterial Infections

Both a retrospective and a prospective population-based study have shown diabetes to be a risk factor for invasive group B streptococcal infection in adults.^{102,103} Skin and soft tissues were the most common local site of infection. Approximately 30% of the cases occurred in patients with diabetes, and the overall case mortality rate was 21–32%. Diabetes is also associated with a 3.7-fold increased relative risk of invasive group A streptococcal infections.¹⁰⁴

Malignant external otitis (MEO) is a pyogenic infection of the ear canal, often with *Pseudomonas aeruginosa*, which is characteristically seen in older diabetic patients with purulent discharge, facial swelling, unrelenting pain, hearing loss, and granulation tissue in the ear canal.^{101,105} The onset may be indolent, and the diagnosis is often delayed.¹⁰¹ In a study by Chandler, 68 of 72 patients

had diabetes.¹⁰⁶ In a more recent study, 21 of 30 patients had evidence of diabetes.¹⁰⁷ Aural irrigation with tap water was reported as a preceding event in 8 of 13 patients in a study by Rubin and coworkers.¹⁰⁸ The mortality rate is cited as 20–40% despite appropriate antibiotics.^{101,105}

Necrotizing fasciitis is another uncommon but potentially lethal infection seen postoperatively and following minor trauma, as well as at injection sites.^{99,101,109} Synergistic infection involving two or more organisms is the rule; however, one organism may cause the condition.¹¹⁰ Organisms may include facultative streptococci, *Bacteroides*, peptostreptococci, and occasionally staphylococci. The perineum, trunk, abdomen, and upper extremities are the sites most commonly involved. Toxicity is often out of proportion to signs. Redness, induration, cyanosis, and necrosis with overlying bullae may be seen. In a study by Baskin and associates,¹¹⁰ 12 of 27 patients with necrotizing soft tissue infection had diabetes. Mortality rates of 21–80% have been reported.^{99,101,110} The most important aspect of treatment is early aggressive surgical debridement.

The prevalence of staphylococcal infections in diabetic patients has been the source of controversy. Gilgor concluded that no well-controlled studies have proved that furunculosis, boils, or carbuncles are more prevalent in patients with diabetes.⁹⁹ In a more recent review, the authors concluded that currently available data do not permit estimation of proportional risk of staphylococcal infection in patients with DM.¹¹¹ A large study from a single center demonstrated an increased rate of cutaneous staphylococcal infections in diabetic patients using continuous subcutaneous insulin infusion (CSII).¹¹² However, an increase in the rate of staphylococcal carriage could not be demonstrated for patients using CSII compared with diabetic patients injecting insulin or normal control subjects.¹¹³ A geographically based study of 551 residents in the San Luis Valley of Colorado also failed to show an increased rate of nasal staphylococcal carriage among patients with diabetes.¹¹⁴

Erythrasma is an infection of intertriginous skin with *Corynebacterium minutissimum*. The organism produces a porphyrin pigment that results in characteristic coral red fluorescence when a Wood's lamp is shined on the skin. The infection is of little medical consequence but has been observed in up to 61% of diabetic patients.⁹⁹ Each of these bacterial infections may be treated with appropriate systemic antibiotics. Erythrasma may be treated with topical or oral erythromycin.

Fungal and Yeast Infection

Candida albicans causes angular cheilitis, glossitis, vulvovaginitis, balanitis, finger web space infection, and paronychia in diabetic patients.¹⁰¹ *Candida* infection appears to be more common in poorly controlled patients with diabetes.⁹⁹ Clinical evidence of candidal paronychia was observed in 9.6% of 250 diabetic women compared with only 3.4% of 500 nondiabetic women.¹¹⁵ *Candida* infections may be treated with oral or topical antifungals. In the case of paronychia, it may be even more important to alter the environment of the proximal nail fold by avoiding wetness (e.g., cotton gloves worn under rubber gloves when working in water) and by using drying agents for treatment, such as 15% sulfacetamide in 50% ethanol (3–4 drops four times per day and each time the hands get wet).

The prevalence of toenail onychomycosis appears to be increased in patients with diabetes.¹¹⁶ The importance of treating dermatophyte infections on the feet of diabetic patients is that they

may provide a portal of entry for subsequent bacterial infections. Topical antifungals usually suffice to control fungal infection on skin adjacent to affected nails, but oral agents are needed to clear the onychomycosis.

Mucormycosis is an infection caused by a ubiquitous fungal organism found primarily in soil and decaying vegetation. It has been repeatedly reported in diabetic patients.^{99,101} In particular, *Rhizopus* and *Mucor* have been observed complicating skin ulcers on legs and hands in diabetic patients. A destructive nasal mucosa and sinus infection called rhinocerebral mucormycosis (RCM) is particularly devastating. Early manifestations include facial or ocular pain and nasal stuffiness with or without discharge. Later manifestations may include proptosis, necrotic lesions on the palate or nasal turbinate, ophthalmoplegia, and vision loss.¹⁰¹ Approximately 75–80% of RCM occurs in diabetic patients with uncontrolled disease.¹¹⁷ Amphotericin B and surgical debridement are the treatments of choice. Mortality rates for RCM have been reported to be 15–34%.¹¹⁸

ERUPTIVE XANTHOMAS

Diabetes is the most common cause of acquired hypertriglyceridemia⁷ (see Chap. 47). Triglyceride-rich chylomicrons are usually rapidly cleared by the action of lipoprotein lipase; however, lipoprotein lipase activity is decreased in uncontrolled diabetes.¹¹⁹ Insulin is necessary for normal clearance of plasma lipoproteins.¹²⁰ Eruptive xanthomas may develop as the skin manifestations of chylomicrons in hypertriglyceridemic patients.^{121,122} Plasma lipoproteins can be shown to enter the skin,¹²³ where they are phagocytosed by macrophages. These macrophages appear as foam cells in the eruptive xanthomas.¹²⁴

Eruptive xanthomas appear as 1- to 4-mm reddish yellow papules on the extensor surfaces of the arms, legs, and buttocks. They are usually asymptomatic, but are a most important clinical sign because they may be the first indication of diabetes. The hypertriglyceridemia responds rapidly to diet and insulin therapy and the eruptive xanthomas usually resolve completely in 6–8 weeks.¹²² Untreated severe hypertriglyceridemia may lead to abdominal pain, pancreatitis, hepatosplenomegaly, lipemia retinalis, hypoxemia, abnormal hemoglobin oxygen affinity, decreased pulmonary diffusing capacities, and psychological changes.¹²⁵

NECROBIOSIS LIPOIDICA (NL)

One of the significant developments in the most recognized skin condition associated with diabetes is its taxonomy. Since Urbach coined the term *necribrosis lipoidica diabeticorum* in 1932,¹²⁶ generations of dermatologists and diabetologists have used the abbreviation “NLD” to refer to this condition. Now in the modern era of computerized literature searches, if one adds the term “diabeticorum” to the search, about 80% of the published papers on the topic for the past 5 years are not retrieved. Many investigators¹²⁷ prefer the term *necribrosis lipoidica*, because many of the patients with this condition do not have diabetes.¹²⁸ Perhaps we eventually will get used to this term as well as the abbreviation “NL.”

NL was associated with diabetes in approximately two-thirds of 171 cases reported from the Mayo Clinic.¹²⁹ Glucose tolerance tests performed on nondiabetic patients revealed another 5–10% with abnormalities in carbohydrate metabolism.¹²⁹ A more recent

series of 65 patients with NL revealed that only 11% had been diagnosed with diabetes after 15 years of follow-up.¹²⁸ In the converse situation, evaluation of unselected patients with diabetes at the Mayo Clinic revealed that only 3 per 1000 diabetic patients had NL.¹²⁹ Similarly, only 3 of 395 patients with diabetes (age 15–55) in a population-based study from Sweden had NL,¹³⁰ and the prevalence of NL in children with T1DM was 1 in 1557 patients in the Scottish Study Group for the Care of the Young Diabetic.¹³¹

The typical clinical presentation is that of multiple (four to eight), asymptomatic, oval, sharply margined, reddish brown plaques over the anterior legs (bilateral 75% of the time) on young (mean age, 30 years) diabetic women (3:1 female to male ratio).¹²⁹ The plaques often slowly enlarge, with the center developing the typical glazed-porcelain sheen with a yellowish hue and prominent telangiectasia (Fig. 53-6). The active margins remain erythematous and slightly elevated. Ulceration occurs in about one-third of diabetic patients with NL, and spontaneous remission is relatively rare (19%).¹²⁹ Clinical variants may be solitary and may be seen on the hands, fingers, forearms, face, scalp, and nipple.^{127,132} When NL is present, it rarely spares the legs (2% of the time).¹²⁹

The clinical presentation is usually the key to diagnosis, but the histology is also characteristic. At times, however, it is difficult to distinguish NL from other necrobiotic conditions such as granuloma annulare. The histopathologic and immunohistochemical features of NL have been succinctly reviewed^{127,133} and contrasted with granuloma annulare (GA).¹³³ The histologic features of NL include poorly defined histiocytic granulomas with necrobiosis in the middle to deep dermis, periodic acid Schiff (PAS)–positive staining in the areas of necrobiosis, and vascular changes consisting of endothelial swelling, fibrosis, and hyalinization. Nerve staining with S-100 is diminished in lesional skin and in the inflammatory perilesional areas.¹³⁴ The latter observation is offered as an explanation for decreased sensation in well-developed plaques of NL.¹³⁵

The pathogenesis of NL remains unknown, but many mechanisms have been proposed and reviewed in detail.¹²⁷ Proposed mechanisms include heredity, microangiopathy, increased production of fibronectin by endothelial cells, increased factor VIII–related antigen, abnormal platelet function and prostaglandin synthesis, accelerated collagen aging, and immune-mediated vasculopathy. Most recently, Saarialho-Kere and associates¹³⁶ studied the pattern of mRNA expression for tissue inhibitor of metalloproteinase 1 (TIMP-1), interstitial collagenase, and 92-kd gelatinase in

FIGURE 53-6. Plaques of necrobiosis lipoidica. The lesion has a typical glazed-porcelain sheen and yellowish hue with prominent telangiectasia.

skin biopsies from lesions of NL and GA. Both disorders are characterized by altered extracellular matrix and degenerative changes in collagen and elastic fibers. Expression of metalloproteinases was noted in early lesions, but not later lesions of NL and GA, suggesting that collagenolysis is an early event in these lesions. There is no evidence that poor glycemic control is a factor in NL,^{129,137} although this has not been extensively studied using newer techniques for subfractionating AGEs from skin biopsies. TcPO₂ values are significantly lower in lesional skin than in adjacent normal skin.¹³⁸

The long list of treatments for NL is evidence that no treatment is the accepted standard of effective care.¹²⁷ Studies of NL therapy generally suffer from small numbers of patients, the absence of controls, or both. Our experience with dipyridamol and aspirin has been disappointing, as was that reviewed by Lowitt and Dover.¹²⁷ High-potency topical steroids may be useful in the early, inflammatory phase of NL. Likewise, injection of triamcinolone in perilesional skin has been used with success¹²⁹; however, care should be exercised with local steroid use because ulceration may occur. Short-term use of systemic steroids has been advocated,¹³⁹ as has pentoxifylline 400 mg three times a day.¹⁴⁰ However, the admonition to "do no harm" may be well advised in this disorder.

The main issues for plaque-type NL are the cosmetic appearance and protection to avoid ulceration. Cover-up products such as Dermablend or Covermark may be useful for special occasions to help cosmetically. Protective padding is well advised for ulcer protection during high-risk activities, and a night-light is useful to prevent inadvertent trauma when using the bathroom at night.¹⁴¹

When ulcers occur in NL, the same principles apply as discussed above for diabetic ulcers. Recently, a report of the successful use of cyclosporine for the treatment of persistently ulcerated NL in two patients was published.¹⁴² For very large or recalcitrant ulcers in NL, excision down to fascia with split-thickness skin grafting appears to be effective and the preferred therapy.¹⁴³

GRANULOMA ANNULARE (GA)

Granuloma annulare is a benign self-limited condition characterized by annular plaques usually seen over the dorsal hands, feet, or ankles. The plaques often consist of a ring of papules, red to reddish purple in color, with clearing or flattening in the center. They may be solitary papules, nodules, or plaques, and on rare occasions present as subcutaneous nodules or perforating lesions.¹⁴⁴ About 15% of patients have more than 10 lesions and 7–10% have generalized lesions.^{144,145} The localized form tends to come on earlier in life (two-thirds prior to age 30) and usually clears within 2 years,¹⁴⁶ whereas in the generalized form the mean age of onset is 52 years, and it rarely clears spontaneously.¹⁴⁵

The pathogenesis of GA remains unknown. Its association with diabetes has long been debated.¹⁴⁷ In a large series from the Mayo Clinic in 1989, Dabski and Winkelmann reported diabetes in 9.7% of 1353 patients with localized lesions of GA, and 21% of 100 patients with generalized GA.¹⁴⁵ In two more recent retrospective studies, 11 of 61 patients (18%)¹⁴⁸ and 10 of 84 patients (12%)¹⁴⁹ with GA had diabetes. A large population-based study of patients with DM would be useful to help resolve the relationship between GA and DM, but the more recent data continue to support the arguments in favor of an association.

Treatment with high-potency topical steroids or steroid injection may be effective for localized GA, but it is usually an asym-

ptomatic self-limited process. Generalized GA may be more pruritic and persistent, and it is certainly more cosmetically disabling. Encouraging results for generalized GA have been reported with PUVA.¹⁵⁰ It should be noted, however, that sunburn has been reported as a precipitating factor for some patients with generalized GA.¹⁴⁵ Limited success has been reported with systemic corticosteroids, chloroquine, potassium iodide, sulfones, niacinamide, and chlorpropamide, as reviewed by Dabski and Winkelmann.¹⁴⁵

A careful history and physical examination should be done with the question of diabetes in mind. It could be argued that a fasting blood sugar should be obtained in older patients with generalized GA. GA lesions have been reported in patients with HIV infection.^{151,152} If risk factors for HIV are present, antibody testing should be considered.

DIABETIC DERMOPATHY

Melin is generally credited with describing atrophic circumscribed lesions localized to the lower extremities¹⁵³ in diabetic patients. They consist of small (2–10 mm), rounded, brownish, atrophic lesions almost exclusively over the pretibial surface of the legs (Fig. 53-7). They have subsequently been referred to most commonly as

FIGURE 53-7. Atrophic "shin spots" or diabetic dermopathy on the legs of a diabetic man.

"shin spots"¹⁵⁴ and diabetic dermopathy.¹⁵⁵ Controversy has surrounded this condition regarding the prevalence, the specificity as a cutaneous marker for diabetes, the relationship to other complications of diabetes, and its relationship to trauma.¹⁵⁶

Prevalence of atrophic shin spots ascertained from diabetic patients in outpatient clinics has ranged from 24–65% for males and 4–39% for females.^{153,154,157,158} The prevalence in nondiabetic control groups was 7% of 104 patients in a hypertension clinic,¹⁵³ 20% of 183 patients in an endocrine clinic,¹⁵⁴ 3% of 100 patients in a dermatology clinic,¹⁵⁷ and 1.6% of 201 healthy medical students.¹⁵⁴ Perhaps the best prevalence data come from a population-based study in which standard skin examinations were performed on the lower extremities of 96% of 395 patients with known diabetes aged 15–50 years from Umea County, Sweden.¹⁵⁸ It is of interest that the University of Umea is where Melin's report originated in 1964. They observed shin spots in 33% of patients with T1DM and 39% of patients with T2DM, compared with 2% of a control group comprised of 100 healthy people, mainly hospital personnel aged 15–50 years. Most authors agree that though the finding is not specific for diabetes, diabetic dermopathy does occur with greater frequency in patients with diabetes. Additionally, there is agreement that it occurs more frequently in men, and the duration of diabetes is directly related to the prevalence of diabetic dermopathy.

The pathogenesis of the condition is unknown. Trauma has been the leading candidate, even though most patients are unaware of associated trauma and the lesions are asymptomatic. Arguments in favor of trauma are supported by the location on the shins and the increased prevalence in men. Melin was unable to produce lesions on the shins of diabetic patients with a rubber hammer and found no lesions on the shins of normal healthy soccer players.¹⁵³ Lithner, however, was able to induce atrophic circumscribed skin lesions at the site of trauma from locally applied heat and cold in patients with diabetes.¹⁵⁹ Perhaps diabetic dermopathy represents a pattern of repair in response to injury or inflammation within the milieu of diabetes.

Melin found an association of atrophic shin spots with other clinical complications of diabetes, including retinopathy, lower extremity vascular disease, and nephropathy.¹⁵³ However, in the other large study to look at this question, Danowski and colleagues found no such associations.¹⁵⁴ In the most recent study of 173 patients with DM (69 with atrophic shin spots), a strong statistical relationship with retinopathy, nephropathy, and neuropathy was reported.¹⁶⁰ The histology is not diagnostic. It shows epidermal atrophy and pigment inclusion but no clear-cut evidence for a vasculopathy in lesional skin by either histology or electron microscopy.¹⁶¹ No treatment is necessary since it is without symptoms or morbidity.

BULLOSIS DIABETICORUM

The abrupt onset of bullae on the extremities has been reported as a rare condition associated with diabetes.¹⁶² The lesions are usually on the toes, feet, and distal lower extremities, but are also observed on the fingers, hands, and forearms. They are unrelated to any apparent trauma or infection and heal without scarring in 2–5 weeks unless they become infected. Although the condition may resolve spontaneously, it may recur over a number of years.¹⁶³

The histopathology is variable, as reviewed by Toonstra.¹⁶³ The level of separation resulting in the bulla may be intraepidermal

or subepidermal. The intraepidermal split may occur anywhere from suprabasally to subcorneally, usually without acantholysis, although spongiosis may be present. Direct immunofluorescence is usually negative.^{163,164}

Because the pathogenesis is unknown and the treatment is supportive wound care, the main significance of this condition is recognition that it is not one of the other blistering disorders of the skin. The differential diagnosis includes bullous impetigo, bullous pemphigoid, pemphigus vulgaris, epidermolysis bullosa acquisita, porphyria cutanea tarda (PCT), bullous erythema multiforme (e.g., due to drugs), and insect bite reaction. A negative culture for staphylococci, a negative direct immunofluorescence on skin biopsy, and compatible histopathology makes this diagnosis by exclusion relatively certain. A porphyrin screen could be considered if other signs of PCT are present. The diagnosis is important because the treatment of a number of the other blistering diseases involves the use of systemic steroids or immunosuppressive therapy, which confers significant risk of toxicity to diabetic patients.

ACQUIRED PERFORATING DERMATOSIS

Acquired perforating dermatosis (APD) has been reported in association with diabetes and renal failure. Rapini and collaborators¹⁶⁵ reviewed a variety of terms used for this group of conditions. They include Kyrle's disease, reactive perforating collagenosis (RPC), perforating folliculitis, and elastosis perforans serpiginosa. Because histology may vary from location to location on the same patient and the pathogenesis is unclear, it appears more logical to consider these conditions together rather than to emphasize differences.

APD is characterized by transepidermal elimination of what appears to be altered collagen. The clinical appearance consists of pruritic papules and nodules on the upper and lower extremities as well as the trunk and, to a lesser extent, the face. The lesions are often perifollicular, as noted in Fig. 53-8. In review of the literature, Faver and associates¹⁶⁶ were able to describe 22 cases considered to be RPC: 72% (16/22 patients) had diabetes with at least one complication (nephropathy, retinopathy, peripheral vascular disease, or cardiomyopathy), 15 patients had nephropathy, and 10 were on dialysis. In a more recent study in which dialysis patients received prospective skin examinations, 11% (8 of 72 patients) were observed to have APD. Seven of the eight patients had DM.

FIGURE 53-8. Acquired perforating dermatosis in a young woman with T1DM who is on dialysis.

These observations are supportive of the association of APD with DM and chronic renal failure, and it suggests that APD may be more common than previously appreciated.¹⁶⁷ The pathogenesis is unclear, but treatment with glycemic control, ultraviolet light, retinoic acid, or topical steroids is at times effective.

GLUCAGONOMA

Glucagonoma is one cause for diabetes that is potentially curable by surgery; hence it deserves mention even though it occurs rarely. This diagnosis should be considered in diabetic patients with a recalcitrant erosive dermatitis, typically involving the central face, groin, friction areas, and the distal extremities.¹⁶⁸ It is usually seen in the clinical setting of weight loss, diarrhea, glossitis, anemia, hypoalbuminemia, and mild DM. Skin biopsy shows epidermal necrosis, edema, and a split in the upper spinous layer, along with a neutrophilic infiltrate.¹⁶⁹ The clinical and histologic features taken together resulted in the term *necrolytic migratory erythema* (NME).¹⁷⁰

Glucagonoma is a tumor of the α (alpha) cells of the pancreas, which secrete glucagon. It is malignant in 60–80% of cases and often is metastatic at the time of diagnosis.¹⁷¹ Early diagnosis is rare because it is not considered by the clinician. Some authors suggest obtaining a glucagon level in any patient with DM and an unexplained rash.¹⁷² The diagnosis is made more difficult by the fact that 15% of patients with glucagonoma do not have DM,¹⁶⁸ and some patients with NME have normal glucagon levels and no evidence of glucagonoma.¹⁷³

In the proper clinical context, the diagnosis can usually be confirmed with a fasting serum glucagon level. The tumors can usually be visualized on CT scan;¹⁷⁴ however, selective celiac axis arteriography is the most useful diagnostic study for localizing the tumor and identifying metastases in the liver.^{175,176} Treatment usually includes surgical excision. Even in metastatic disease, cytoreductive surgery often results in long remission.¹⁷² Chemotherapy may be helpful, and long-acting somatostatin analogues result in good symptomatic relief even though they have no effect on tumor size.¹⁷⁷

INSULIN INJECTION COMPLICATIONS

Strong evidence has been presented that intensive insulin therapy effectively delays the onset and slows the progression of microvascular disease in T1DM^{178,179} (see Chap. 54). Multiple daily insulin injections have become the norm, and external insulin pumps are an effective alternative for intensive insulin therapy.¹⁷⁹ Management of the skin complications of insulin therapy may become more problematic with intensive insulin therapy. In older literature, the incidence of skin complications was given as 10% and 56% of all patients with diabetes receiving conventional bovine and pork insulin, respectively.¹⁸⁰ That incidence has decreased substantially with the use of purified pork and bovine insulin as well as with human insulin (HI).^{181–183}

Lipoatrophy with less pure, earlier insulin preparations was reported in 16% of patients,¹⁸⁴ whereas with highly purified insulin it occurred in 0–2.5% of cases.^{182–184} It is sufficiently uncommon with use of HI that case reports and letters regarding its occurrence continue to appear.^{185,186} Lipoatrophy has been attributed to local immune complex formation and complement fixation with release of lysosomal enzymes in response to a presumed antigenic component of the less purified insulins.¹⁸⁷ As noted, however, it does con-

tinue to occur with highly purified insulin and HI. Chantelau and coworkers reported a case in which lipoatrophy resulted from injection of intermediate- and long-acting HI. The authors successfully used continuous subcutaneous insulin injection (CSII) with regular HI, and speculated that the shorter-acting insulin may have been responsible for the improvement.¹⁸⁵

Lipohypertrophy has not decreased with the use of highly purified insulin and HI. In fact, at one center lipohypertrophy was observed in 14% of patients using conventional insulin, whereas 22% of patients injecting highly purified insulin developed lipohypertrophy.¹⁸⁴ At another center lipohypertrophy was observed in 76 of 281 (27%) patients injecting purified insulin.¹⁸³ Lipohypertrophy is thought to occur because of a local anabolic effect of insulin that promotes fat and protein synthesis. The problem can usually be alleviated by rotation of injection sites, but the hypertrophic sites are often repeatedly used by the patients because they tend to be less painful. However, patients should be discouraged from using the sites with lipohypertrophy because the insulin absorption can be delayed or inconsistent.^{188,189}

Local and systemic allergic reactions have been reported with insulin injections. Fortunately, local reactions are by far the most common. A variety of factors may be involved, including contaminating proteins,¹⁹⁰ zinc,¹⁹¹ and protamine,¹⁹² as well as insulin itself (including HI).¹⁹³ Such allergic reactions are usually IgE-mediated,¹⁹⁴ although patients may have IgE antibodies to insulin without clinical evidence of an adverse reaction,^{190,195} and IgE antibodies have been measured in sera from allergic nondiabetic individuals with affinities and concentrations similar to those seen in diabetic patients.^{196,197} Local reactions to insulin are often transient and of no major significance. They usually present as a wheal and flare within 30 minutes. Systemic allergic reactions, though rare, are potentially life-threatening. They include urticaria, angioedema, anaphylaxis, and the Arthus reaction.¹⁹⁸ Although highly purified insulin and HI are less immunogenic, allergic reactions are still observed.¹⁹³ Intradermal testing may be used to find an insulin preparation to which the patient does not react.^{193,199} Desensitization techniques are useful for generalized insulin allergies.¹⁹⁹ Systemic steroids and antihistamines are occasionally required.^{181,200}

Nonimmunologic cutaneous reactions have been reported to insulin injection as well. They include infections (e.g., *S. aureus*, *S. epidermidis*, and *M. chelonae*),^{112,201} zinc granulomas and sterile abscesses,²⁰² silicon oil from disposable syringes,²⁰³ and keloid formation, as well as pigmentation that can resemble acanthosis nigricans.²⁰⁴

Continuous subcutaneous insulin infusion (CSII) deserves special mention because skin complications are the most common reason the treatment is discontinued.²⁰⁵ Chantelau and collaborators²⁰⁶ reported on 116 patients with T1DM followed for a mean period of 4.5 years. They reported 134 cases of skin inflammation or infection during the study period: 51% developed redness at the catheter sites, 19% developed subcutaneous nodules, and 48% had whitish scars secondary to previous infections. In an earlier study, catheters were cultured from 40 patients during 120 separate examinations. *S. epidermidis* was recovered in 42 cases and *S. aureus* in 15 cases.¹¹² Pyogenic skin inflammation was described by van Faassen and coworkers¹¹³ in 48% of 50 patients treated with CSII, compared with 6% of the insulin-injecting patients and 3% of healthy volunteers. Recommendations regarding skin care with CSII include needle change every 48 hours, no catheter reuse, hand washing before insertion of needles, antiseptic preparation of needle insertion sites, and sterile covering of the needles.¹¹²

Relationship of Glycemic Control to Diabetic Complications

Jay S. Skyler

The most important issue facing clinicians who care for patients with diabetes is the extent to which the frequency or severity of chronic complications can be influenced by the degree to which glycemia is controlled. For many years, this was one of the most controversial questions in the field of diabetes. This was in spite of the fact that substantial accumulated evidence demonstrated that the frequency, severity, and progression of retinopathy, nephropathy, and neuropathy are related to the degree of hyperglycemia over time. That evidence came from epidemiologic, clinical, and pathologic studies in human beings; from studies using animal models of diabetes; and from the elucidation of a number of biochemical mechanisms, putatively involved in the pathogenesis of these complications, that are influenced directly by hyperglycemia. Yet controversy on this subject continued, principally because there were no longitudinal prospective randomized intervention studies. That lacuna no longer exists. Now it has been unequivocally established—by randomized controlled clinical trials—that careful control of glycemia indeed can lessen the risk of the microangiopathic and neurologic complications of diabetes. This has been demonstrated for type 1 diabetes mellitus (T1DM) in the landmark Diabetes Control and Complications Trial (DCCT), the Stockholm Diabetes Intervention Study (SDIS), and a number of smaller prospective intervention studies. It also has been demonstrated for type 2 diabetes mellitus (T2DM) by the United Kingdom Prospective Diabetes Study (UKPDS) and the smaller Kumamoto Study from Japan.

A growing number of epidemiologic studies also have shown that there is a relationship between degree of glycemia and the incidence and prevalence of macrovascular complications of diabetes (i.e., cardiovascular disease, cerebrovascular disease, and peripheral vascular disease). Indeed, the relationship between glycemia and macrovascular disease extends throughout the range of glycemia, including nondiabetic individuals. Yet, the large randomized controlled clinical trials have failed to show convincingly that macrovascular disease is impacted by glycemic control. However, some analyses suggest that the DCCT and UKPDS do show such an effect.

In this chapter, the focus will be on intervention studies, specifically, randomized controlled clinical trials. However, because of their historical importance, the WESDR Study and the Brussels study also are discussed.

EPIDEMIOLOGIC AND OBSERVATIONAL STUDIES

Brussels Study

The Brussels Study, reported in 1978, represented a landmark in delimiting the question of the relationship between glycemia and diabetic complications.¹ Between 1947 and 1973, Jean Pirart of Brussels, Belgium, personally followed 4400 patients for up to a quarter century, and meticulously recorded observations on their glycemic control and the appearance of diabetic complications. His striking observations demonstrated that the frequency and severity of diabetic retinopathy, nephropathy, and neuropathy were related to both duration of disease and to cumulative glycemic control. Poor control assessed cumulatively over the years was associated with a higher prevalence and incidence of microangiopathy and neuropathy, especially severe retinopathy. Yet, Pirart did not randomly allocate patients *a priori* to either “good” or “poor” control. Thus it was impossible to exclude the possibility that patients with mild diabetes achieved “good” control and escaped complications, while patients with more severe diabetes achieved “poor” control and suffered more complications. Moreover, the study was conducted in an era prior to the availability of glycated (glycosylated) hemoglobin determinations to assess glycemic control.

Other Epidemiologic and Clinical Studies

Subsequently, many other similar clinical studies, as well as a large number of both cross-sectional and longitudinal epidemiologic studies have reported relationships between glycated hemoglobin and incidence and prevalence of retinopathy, nephropathy, and neuropathy.

Wisconsin Study

One of the longest, largest, and most carefully conducted of these longitudinal epidemiologic studies is the Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR).²⁻²² The Wisconsin study is a large population-based study which has reported on the evolution of diabetic complications, particularly retinopathy, among diabetic patients receiving community care in 11 counties in southern Wisconsin.²⁻⁶ The sample included all diabetic subjects

with onset before 30 years of age (younger-onset cohort; $n = 1210$) and a probability sample of those with onset after 30 years of age (older-onset cohort; $n = 1780$ of 5431 patients with a confirmed diagnosis of diabetes). From this sample, 79.1% ($n = 2366$) underwent baseline evaluation in 1980–1982. Four-year follow-up evaluations were performed in 1984–1986 on 1878 individuals, 95.7% of those evaluated at baseline and still alive. Ten-year follow-up evaluations were performed in 1990–1992 on 1298 individuals, 88.7% of those evaluated at baseline and still alive.⁶ Because of the high death rate in the older cohort, only the younger cohort was re-examined at 14 years in 1995–1996, with 634 subjects participating.¹¹ Some information also was obtained from an additional 309 subjects from the older cohort.^{12,19} Evaluations were conducted in a special van, and included collection of historical data, blood pressure, visual acuity, seven-field fundus photography, measurement of glycosylated hemoglobin (HbA_{1c}), and urine protein.

The younger-onset cohort presumably includes mostly individuals with T1DM. For many analyses, the older-onset cohort is divided into those treated with insulin (46.3% of the original probability sample) and those not treated with insulin (53.7% of the original probability sample). Those not treated with insulin presumably have T2DM, while those treated with insulin presumably are a mixed group with most probably having T2DM.

Among the many findings reported by the WESDR investigators, the most notable describe the relationship of hyperglycemia (both baseline HbA_{1c} and change of HbA_{1c} between baseline and 4-year follow-up) and (a) incidence and progression of retinopathy, (b) incidence of nephropathy, (c) nerve function and incidence of lower extremity amputations, (d) hospitalizations, and (e) survival. Most of these analyses evaluated the influence on a given outcome measure of HbA_{1c} divided into quartiles.

In all three cohorts (younger-onset, older-onset treated with insulin, older-onset not treated with insulin), there was at both 4⁷ and 10 years' follow-up⁸ a statistically significant relationship between baseline HbA_{1c} and (a) incidence of retinopathy, (b) progression of retinopathy by two or more steps on a 15-step scale, and (c) progression to proliferative retinopathy. The 10-year data for progression to proliferative retinopathy are shown in Fig. 54-1, as an ex-

FIGURE 54-1. The relationship of 10-year progression to proliferative diabetic retinopathy (PDR) by quartile of glycosylated hemoglobin (1st quartile □, 2nd quartile ■, 3rd quartile ▨, 4th quartile ▩) at baseline in the Wisconsin Study. This is shown in three cohorts: the younger-onset group taking insulin, the older-onset group taking insulin, and the older-onset group not taking insulin. In each cohort the p values for the Mantel-Haenszel test of trend are significant. (Adapted with permission from Klein et al.⁸)

ample of the relationships observed. At the 10-year follow-up, they also reported a statistically significant relationship between baseline HbA_{1c} and macular edema in the younger-onset cohort and the older-onset cohort considered as a whole,⁹ and visual loss in the younger-onset cohort and the older-onset cohort treated with insulin, but not in the older-onset cohort not treated with insulin.¹⁰ In the older-onset cohort, however, nondiabetic causes of visual loss (e.g., cataract, glaucoma, macular degeneration) complicated data interpretation. As noted, at 14 years, only data from the younger-onset cohort have been reported.^{11,12} At that time, progression of retinopathy was more likely with elevated HbA_{1c} at baseline, or an increase in HbA_{1c} from the baseline to the 4-year follow-up. Increased risk of proliferative retinopathy or incidence of macular edema was associated with higher HbA_{1c} at baseline, and an increase in HbA_{1c} between the baseline and 4-year follow-up examination. Lower HbA_{1c} at baseline was associated with improvement in retinopathy. Visual loss was associated with higher HbA_{1c} levels.

In both the younger-onset cohort and the older-onset cohort, there was a statistically significant relationship between baseline HbA_{1c} and 4-year incidence of gross proteinuria^{13,14} and microalbuminuria,^{15,16} and 10-year incidence of gross proteinuria.² In the younger-onset cohort, but not in the older-onset cohort, there was a statistically significant relationship between baseline HbA_{1c} and 10-year incidence of decline in creatinine clearance and develop-

FIGURE 54-2. The effect on risk of development of complications of a 1% increase in glycosylated hemoglobin at baseline in (A) the younger-onset group, and (B) the older-onset group, in the Wisconsin Study. In each case the points are the estimate and the bars represent the 95% confidence interval of the estimate. (Adapted with permission from Klein.²)

ment of renal insufficiency.¹⁷ The absence of a relationship with glycemia in the older-onset cohort may have been because the overall event rate for renal failure was low (1.8%).

In terms of nerve function, in all three cohorts, there was at 10 years' follow-up a statistically significant relationship between baseline HbA_{1c} and loss of tactile sensation, whereas the relationship between baseline HbA_{1c} and loss of tactile sensation was statistically significant only in the younger-onset cohort and the older-onset cohort on insulin.³ In both the younger-onset cohort and the older-onset cohort considered as a whole, there was a statistically significant relationship between baseline HbA_{1c} and incidence of lower extremity amputation both at 10 years¹⁸ and 14 years.¹⁹

Factors from the 4-year examination were studied for their ability to predict hospitalization at the 10-year examination. HbA_{1c} level predicted hospitalization.²⁰

In terms of mortality,^{3,21} in the younger-onset cohort, after controlling for other risk factors in proportional hazard models and considering underlying cause of death, HbA_{1c} was significantly associated with 10-year mortality from all causes, from diabetes *per se*, and from ischemic heart disease. In the older-onset cohort, HbA_{1c} was significantly associated with 10-year mortality from all causes, from diabetes *per se*, from ischemic heart disease, and from stroke.

The data from the Wisconsin study demonstrate a strong and consistent relationship between glycemia and the incidence and progression of microvascular (diabetic retinopathy, loss of vision, and nephropathy) and macrovascular (amputation and cardiovascular disease mortality) complications in people with both T1DM and T2DM. The relationship was such that the investigators could calculate the effect on risk of development of complications of a 1% increase in baseline glycosylated hemoglobin, as illustrated in Fig. 54-2.²

INTERVENTION TRIALS

The Brussels Study mentioned earlier¹ stimulated the initiation of a number of prospective trials designed to examine the influence of improved glycemic control, achieved with intensive insulin therapy (often, but not always, using an insulin infusion pump), in contrast to unchanged conventional therapy. These were generally initiated in the early 1980s, and most (except one from the mid- to late

1970s) have used glycosylated hemoglobin determinations to assess integrated glycemic control. These early trials mostly involved subjects with T1DM.

Three clinical trials have studied subjects with T2DM. One of these, the Veterans Administration Cooperative Study on Glycemic Control and Complications in Type 2 Diabetes Mellitus (VACSDM), was unfortunately aborted after the pilot phase due to lack of funding.^{22,23} After a long hiatus, it is finally again under way.²⁴ The large United Kingdom Prospective Diabetes Study (UKPDS) was completed in 1998. It will be discussed in detail. The smaller Kumamoto Study also will be discussed.

Intervention Trials: Type 1 Diabetes

Meta-Analysis

In 1993, Wang and colleagues^{25,26} reported a formal meta-analysis of published randomized controlled trials that evaluated the effects of intensive glycemic control of T1DM on the progression of diabetic retinopathy and nephropathy, and the risks of severe hypoglycemia and diabetic ketoacidosis. These authors performed a search of the English language literature from 1966 through 1991 and identified 32 potential studies. Sixteen reports met their inclusion criteria of being randomized clinical trials with sufficient follow-up data for retinopathy and/or nephropathy to permit analysis. These 16 reports used in the meta-analysis contain data from 12 independent randomized controlled trials. The overall difference in the risk of retinopathy or nephropathy progression was analyzed, and the overall difference in the incidence of hypoglycemia or diabetic ketoacidosis was estimated. Table 54-1 summarizes the results of the meta-analysis. When compared to conventional control, intensive therapy reduced glycosylated hemoglobin (%) by 1.4 with a 95% confidence interval ranging from 1.1–1.8. The analysis showed that compared to conventionally treated patients, after more than 2 years of intensive therapy the risk of retinopathy progression was significantly lower (odds ratio [OR] 0.49; 95% confidence interval, 0.28–0.85). Seeking evidence of early worsening of retinopathy, the analysis found that in the intensive therapy group, the risk of retinopathy progression was insignificantly higher after 6–12 months of intensive control. In studies that assessed albumin excretion rate, the risk of nephropathy progression was decreased significantly in the intensive therapy group (OR 0.34; 95% confidence interval, 0.20–0.58). The authors

TABLE 54-1. Formal Reported Meta-Analysis Results

		Studies	Subjects	OR	95% CI	p

Hypoglycemia	Severe	6	347	+9.1	(−1.4, 19.6)	
DKA	In CSII	3	144	+12.6	(8.7, 16.5)	

Comparison of intensive therapy to conventional control (odds ratio [OR]) for retinopathy progression (after 6–12 months of intensive therapy, after more than 2 years of intensive therapy, and for progression to proliferative retinopathy or laser treatment) and for nephropathy progression (including all eligible trials, and limiting analysis to studies that measured changes in albumin excretion rate [AER]). Comparison of intensive therapy to conventional control (absolute change in incidence) for severe hypoglycemia and for diabetic ketoacidosis in those who received continuous subcutaneous insulin infusion (CSII). The 95% confidence interval (CI) and p value for significance (where available) are shown.

concluded that long-term intensive glycemic control significantly reduced the risks of diabetic retinopathy and nephropathy progression among T1DM patients when compared with randomly assigned controls.

Review of Studies

The studies discussed in this section are listed in Table 54-2. They include those reviewed in the above meta-analysis (with updated data on some), three trials published since the meta-analysis (Oslo-2A, Oslo-2B, and the DCCT), one apparently missed by the meta-analysis (Italian Multicenter), and one nonrandomized but prospective study (Dallas). Several of these studies have included neurologic endpoints, lipid levels, and other parameters. The bulk of this discussion, however, relates to endpoints in the eyes and kidneys, which are easier to assess.

Steno Studies

Under the leadership of Torsten Deckert, investigators at the Steno Memorial Hospital in Gentofte, Denmark, conducted two independent studies in 70 patients with T1DM.²⁷⁻³³ In both of these studies, subjects were randomly allocated to either unchanged conventional therapy (CT) or improved metabolic control using continuous subcutaneous insulin infusion (CSII). In the first study, initiated in 1980, 34 subjects were enrolled on the basis of having moderately advanced background diabetic retinopathy. In the second study, initiated in 1983, enrollment (of 36 subjects) was based

on the presence of microalbuminuria. In the retinopathy study, in the CSII group, there was consistent improvement in renal function studies after 6 months, 1 year, and 2 years.²⁷⁻²⁹ On the other hand, there was transient deterioration in retinal morphology, characterized by the appearance of soft exudates, indicative of retinal infarction, at the 1-year follow-up in the CSII group. Yet by 2 years, there was a marginally significant trend towards stabilization or improvement in retinal morphology in the CSII group, in contrast to progressive deterioration in the CT group.²⁹

In the Steno microalbuminuria study, over 2 years 5 of 18 patients randomized to CT progressed from microalbuminuria to clinical nephropathy, defined as dipstick-positive proteinuria.³⁰ In contrast, in the CSII group, none of the 18 patients so progressed, a statistically significant difference. Moreover, if one includes in this analysis those subjects in the Steno retinopathy study who also had microalbuminuria at baseline,³¹ a total of 10 of 25 subjects treated with CT progressed from microalbuminuria to clinical nephropathy by 2 years, compared to a total of 1 of 26 subjects treated with CSII ($p < 0.001$).³²

A subsequent report updated these observations after follow-up of 8 years for subjects initially enrolled in the retinopathy study and after 5 years for subjects initially enrolled in the microalbuminuria study.³³ Interestingly, there was sustained difference between the groups in glycemic control. Of the total cohort at long-term follow-up, 12 of 33 assigned to CT had developed proliferative retinopathy, in contrast to 8 of 36 assigned to CSII, but

*n = number of subjects enrolled at start and available for analysis at end.

†Outcomes assessed: E = eyes, K = kidneys, N = nerves, BM = basement membrane width (muscle capillary).

‡Glyco-Hb% = ending glycated hemoglobin (%) for control (Con) and intensive (Int) groups (FBG = fasting plasma glucose in mg/dL for study where glyco-Hb not available).

§Entry criteria—for eyes: N = normal, NP = nonproliferative (background) retinopathy, P = proliferative retinopathy; for kidneys: N-Cr = normal serum creatinine, AER = albumin excretion rate (mg/24 h), UPE = urine protein excretion rate (mg/24 h), -Dipstick = dipstick negative for protein, ↑ = increased, GFR = glomerular filtration rate, -Ren Dis = negative history of renal disease.

¶Outcome: for intensive therapy: Benefit = statistically significant benefit; Trend = trend (not statistically significant) of benefit; No Δ = no change or no difference.

#Refs = references.

this difference is not significant. On the other hand, the renal data are astounding. It turned out that no subject with low-range microalbuminuria (30–99 mg/24 h) at the outset progressed to proteinuria, regardless of treatment assignment. Among the 19 subjects with high-range microalbuminuria (100–300 mg/24 h) at the outset, all 10 of the subjects on CT had progressed to proteinuria (and had done so by 2 years' follow-up) and 7 of the 10 had developed hypertension, while only 2 of 9 subjects on CSII had similarly progressed to proteinuria and only 1 had hypertension. The differences for proteinuria and hypertension were significant, both with $p < 0.01$.

Kroc Group Study

In 1981 six centers in the United States and United Kingdom, led by Harry Keen of Guy's Hospital in London, combined under the aegis of the Kroc Foundation to conduct a randomized pilot trial comparing CT to CSII in 68 subjects with T1DM and mild to moderate background retinopathy.^{34–37} After 8 months, they found deterioration of retinopathy in the CSII group,³⁴ which again proved to be transient, so that by 2 years' follow-up, the two groups were indistinguishable, with a trend towards lesser deterioration in the CSII group.³⁶ Moreover, they found that in subjects with microalbuminuria at the outset, there was an improvement in albumin excretion rate in the CSII group with no change in the CT group.^{34,37}

Oslo Studies

The original Oslo study was initiated by Kristian Hanssen and his colleagues at the Aker Hospital in Oslo, Norway in 1980. In it, 45 subjects with T1DM were randomized to one of three treatments: conventional (CT) twice-daily insulin, multiple insulin (MI) injections (4–5/d), or CSII.^{38–46} The randomization was maintained for 41 months, after which subjects could choose their own treatment. This study also demonstrated a transient deterioration in retinopathy with CSII,³⁹ with the 2-year data showing less progression of retinopathy in the MI and CSII groups than in the CT group,⁴⁰ but no significant difference in retinopathy at 41 months.⁴¹ Follow-up of the original study cohort continued through 8 years, by which time treatment assignment was no longer in effect. That long-term follow-up showed that retinopathy outcome was related to both baseline glycemic control and mean glycemic control over the duration of follow-up.⁴²

In the original Oslo study, mean urinary albumin excretion was only slightly elevated at the start of the study, but after 3–4 years showed a statistically significant decline in the CSII group, but not the other two groups.⁴³ Long-term follow-up of the original cohort after 7 years, by which time treatment assignment was no longer in effect, did show albumin excretion to be related to both baseline glycemic control and mean glycemic control over the 7-year follow-up period.^{44,45} Neurologic outcomes were also assessed after 8 years.⁴⁶ It was found that there was a significant reduction in peripheral motor and sensory nerve conduction velocity in subjects with poorer glycemic control. Lowering of glycemia retarded the deterioration.

A second Oslo study randomized to CSII or CT 30 subjects with T1DM and early incipient nephropathy manifested by microalbuminuria.^{47,48} There have been two reports from these subjects, each assessing novel outcome measures. In one, glomerular charge selectivity was measured in 23 subjects over a 12-month period.⁴⁷ The microalbuminuric subjects had reduced (compared to normal) glomerular charge selectivity at baseline, which was cor-

rected by improved glycemic control. The second report described the results of serial renal biopsies performed in 18 subjects in this series at baseline and after 24–36 months.⁴⁸ With improved glycemic control, there was less increase in basement membrane width. Moreover, in the CT group but not the CSII group there was an increase in matrix/mesangial volume fraction and matrix star volume. There was a close relationship between glycemia and progression of glomerular morphological changes.

Stockholm Study

In this study, the Stockholm Diabetes Intervention Study (SDIS) conducted by Per Reichard and Urban Rosenqvist in Stockholm, Sweden, initially (in 1982) 102 subjects with T1DM, background diabetic retinopathy, normal serum creatinine, and unsatisfactory glycemic control were randomly allocated to either standard insulin treatment or improved metabolic control using intensified insulin treatment. They were evaluated at baseline, at 18 months, at 3 years, at 5 years ($n = 96$), and at 7.5 years ($n = 89$).^{49–57} Follow-up reports after 10 years also have appeared, although during the last 2.5 years excellent glycemic control was sought in all subjects.^{58,59}

In the experimental group with intensive treatment, over the initial 7.5 years of the study, mean glycosylated hemoglobin (HbA_{1c}) (upper limit of normal 5.7%) was 7.1% (versus a baseline value of 9.5%), while the control group with standard treatment was 8.5% (versus a baseline value of 9.4%), the difference between groups being highly statistically significant ($p < 0.001$). During the subsequent 2.5 years, the HbA_{1c} values in the two groups converged slightly, with the previous intensive group rising to 7.3% and the previous standard group falling to 8.1%, still a significant difference ($p < 0.001$).

During the active 7.5-year treatment phase, cumulative rates of development of serious retinopathy^{51,52,54} (i.e., that requiring laser photocoagulation) were 52% with standard treatment and 27% with intensive treatment, for a risk reduction of 48% with intensive treatment. The risk reduction for decreased visual acuity was 67%. When other variables influencing retinopathy progression were controlled for in logistic regression analysis, the effect of assignment to intensified treatment resulted in a risk reduction of 60%. In multivariate analysis, it was found that for every 1% increase in HbA_{1c} during the period encompassing 6–60 months in the study, there was a 2.4-fold increased risk of developing serious retinopathy.

During the active 7.5-year treatment phase, cumulative rates of development of nephropathy^{50,52,54} (i.e., an albumin excretion rate greater than 200 $\mu\text{g}/\text{min}$) were 19.6% with standard treatment and 2.3% with intensive treatment, for a risk reduction of 88% with intensive treatment. When other variables influencing retinopathy progression were controlled for in multivariate analysis, the effect of assignment to intensified treatment resulted in a risk reduction of 90%. Six of the subjects in the standard treatment group and none in the intensive treatment group developed nephropathy with a glomerular filtration rate below the normal range.

There was not a statistically significant difference in the rate of development of clinical neuropathy⁵⁴ during the active 7.5-year treatment phase. However, during the course of the study, deterioration in nerve conduction velocities (tibial, peroneal, sural nerves) was greater in the standard treatment group than the intensive treatment group. Cardiovascular autonomic nerve function was associated with lower HbA_{1c} , and after a mean of 11.4 years, autonomic function was better in the intensively treated group.⁵⁸

Early indices of atherosclerosis were explored in a subset of SDIS subjects.⁵⁷ Carotid arteries were scanned for plaques, intima-media thickness was measured, and arterial wall stiffness was calculated. Patients in the standard treatment group had stiffer arteries ($p = 0.011$) and thicker intima-media in the common carotid artery ($p = 0.009$) than those in the intensive treatment group. Patients with lower HbA_{1c} generally had better endothelial function ($p = 0.028$) and less stiff arteries ($p = 0.009$).

When the subjects were evaluated after 10 years, cumulative rates of development of serious retinopathy (63% versus 33%, $p = 0.003$), nephropathy (26% versus 7%, $p = 0.012$), and symptoms of neuropathy (32% versus 14%, $p = 0.041$) all were higher in the standard treatment group than the intensive treatment group.⁵⁹

Other than the DCCT, of randomized controlled clinical trials designed to examine the influence of glycemic control on diabetic complications in T1DM, the SDIS is the largest trial and had the longest duration. It demonstrated that intensive insulin treatment retards the development of retinopathy and nephropathy, slows the rate of deterioration of nerve function, and perhaps positively impacts on early changes of atherosclerosis.

Oxford Study

The Oxford/Aylesbury (England) study group report in 1983 involved random assignment of 74 patients with insulin-treated diabetes (type 1 and type 2) and background retinopathy into two groups: usual diabetic care (group U) and more intensive care (group A) using basal Ultralente[®] insulin and preprandial regular insulin.⁶⁰ Group A achieved lower glycosylated hemoglobin levels than group U. Group A also showed statistically better preservation of renal and sensory nerve function, as manifested by absence of change in creatinine clearance and vibratory perception threshold, parameters which showed some deterioration in group U. There was no significant difference in progression of retinopathy.

Aarhus Studies

The Aarhus (Denmark) group studied 24 subjects with T1DM and minimal or no retinopathy at the outset.^{61,62} They were randomly allocated to standard insulin therapy (CIT) or CSII. Both their 1-year and 3-year reports showed minimal progression of retinopathy, with no statistical difference between the groups. The 1-year report found that elevated glomerular filtration rate was significantly improved in the CSII group, which also showed a decrease in albumin excretion rate that failed to reach statistical significance.

A separate study, also conducted in Aarhus, examined the influence of glycemic control on renal function in 24 subjects with T1DM.⁶³ Prior to intervention, there was hyperfunction manifested by hyperfiltration and nephromegaly. Elevated glomerular filtration rate was significantly reduced in the CSII group, whereas there was no reduction in the elevated renal plasma flow or nephromegaly.

Italian Study

The Italian National Research Council Study Group on Diabetic Retinopathy, comprising investigators at the Universities of Padua, Milan, and Perugia, studied 38 subjects with T1DM and ischemic background retinopathy, who were matched in pairs for gender, age, diabetes duration, and retinal status.⁶⁴ The pairs were then randomly assigned to conventional therapy (CT) or CSII, and followed every 6 months for 2 years. Their report in 1989 demon-

strated significant difference in glycemic control, and less deterioration of retinopathy in the CSII group.

Naples Study

Another Italian group in Naples randomized 44 subjects with T1DM and mild to moderate background retinopathy to usual conventional therapy (UCT) or intensified conventional therapy (ICT), and admitted them for 24-hour glucose profiles at baseline and after 1, 3, and 5 years.⁶⁵ In this study, improved glycemic control did not prevent progression of retinopathy, which was similar in both groups.

Paris Study

An important study from Hotel Dieu in Paris was the first attempt at a prospective randomized study of diabetic retinopathy in T1DM.^{66,67} This study evaluated progression of background retinopathy in 52 subjects and reported that attempts at careful control resulted in slower progression over 50 months of follow-up. Unfortunately, the study was marred by both a relatively crude endpoint (number of microaneurysms) and by a high rate of crossover between groups.⁶⁸ It also antedated the era of glycosylated hemoglobin measurements.

Guy's Study

A study from Guy's Hospital randomized 12 patients with normal albumin excretion rates, but increased glomerular filtration rates, to CSII or UCIT.⁶⁹ They found that after 1 year, improved control in the CSII group resulted in normalization of glomerular filtration rate, but persistence of increased renal size.

Helsinki Study

A study from Helsinki enrolled 65 subjects with T1DM in a crossover study that spanned 1 year.⁷⁰ The duration was too short to see a beneficial effect on retinopathy. However, what was evident was an early worsening of retinopathy seen in other studies as a transient deterioration.

Dallas Study

The Dallas Diabetes Prospective Trial (DDPT) was initiated by Philip Raskin and colleagues in the early 1980s.⁷¹⁻⁷⁶ Patients with T1DM were offered the opportunity to participate in an intensive treatment program using CSII. Thirty accepted, while 24 declined, remaining on their existing conventional treatment (CT), but agreed to follow-up evaluations over 4 years. Thus the DDPT is a nonrandomized, but prospective study. In it, there was sustained improvement in glycemic control in the CSII group, and no change in the CT group. There have been many reports from this study, and they have demonstrated, among other things, the following statistically significant findings regarding microvascular complications: (1) Measurement of capillary basement membrane (CBM) width, thickening of which is the histologic hallmark of microangiopathy, showed there was thinning of thickened CBMs in the CSII group, in contrast to progressive thickening of CBMs in the CT group;^{71,72} (2) there was less progression of retinopathy with CSII (i.e., stabilization or improvement in retinopathy in the CSII group), in contrast to stabilization or deterioration in the CT group;^{73,74} (3) among subjects with microalbuminuria at the outset, there was stabilization in the CSII group, and increased albumin excretion in the CT group;⁷⁴ and (4) there was improvement in nerve function in the CSII group.^{75,76}

The Diabetes Control and Complications Trial (DCCT)

The DCCT examined whether intensive treatment with the goal of maintaining blood glucose concentrations close to the normal range could decrease the frequency and severity of diabetic microvascular and neurologic complications.⁷⁷⁻⁸⁸ It was conducted under the auspices the U.S. National Institutes of Health—specifically the National Institute of Diabetes, Digestive, and Kidney Diseases (NIDDK)—with the support of the National Heart, Lung, and Blood Institute, the National Eye Institute, the National Center for Research Resources, and various corporate sponsors. The DCCT was designed with sufficient statistical power to draw a relatively firm conclusion. The DCCT was conducted in 29 centers across North America (26 in the United States and 3 in Canada). Enrollment began in the early 1980s. A total of 1441 subjects with T1DM were enrolled. Of these, 726 subjects were recruited within the first 5 years after developing diabetes (mean duration at entry = 2.5 years) and had no evidence of diabetic retinopathy or of microalbuminuria at baseline (the primary prevention cohort). Another 715 subjects were recruited within the first 15 years (mean duration at entry = 8.8 years) after developing diabetes and had mild to moderate background diabetic retinopathy with either normoalbuminuria or microalbuminuria (the secondary intervention cohort). Subjects had to be willing to accept random allocation to treatment group and maintain that treatment assignment for the duration of the study. They were randomly assigned either to intensive therapy or to conventional therapy. Intensive therapy involved insulin administered either by continuous subcutaneous insulin infusion (CSII) with an external insulin pump or by multiple daily insulin injections (MDI) (three or more injections per day), guided by frequent self-monitoring of blood glucose (SMBG) 3–4 times daily, with additional specified samples including a weekly overnight sample; meticulous attention to diet; and monthly visits to the treating clinic. Conventional therapy involved no more than two daily insulin injections, urine glucose monitoring or SMBG no more than twice daily, periodic diet review, and clinic visits every 2–3 months. The subjects were followed for a minimum of 4 years and a maximum of 9 years, with a mean follow-up of 6.5 years (a mean of 6 years in the primary prevention cohort and of 7 years in the secondary intervention cohort), for a total of approximately 9300 patient-years of observation. Of 1430 subjects alive at the end of the study, 1422 came for evaluation of outcomes. Throughout the study, 98–99% of available data were collected.

The experimental group treated with intensive therapy achieved a median glycosylated hemoglobin (HbA_{1c}) throughout the study of approximately 7.2% versus a value in the control group treated with conventional therapy of approximately 9.1% ($p < 0.001$) (Fig. 54-3).⁷⁷ The upper limit of normal, and treatment target in the intensive group, was 6.05%. Thus even in the intensive group, the goal of normalization of HbA_{1c} was not achieved. Yet the “glycemic separation,” or difference between the two groups, was statistically significant throughout the study. The mean blood glucose, obtained on periodic glucose profiles, was 155 mg/dL in the intensive group and 231 mg/dL in the conventional group, whereas the corresponding value for nondiabetic individuals is 110 mg/dL. (During pregnancy, all subjects received intensive therapy. There were a total of 287 pregnancies, among 189 subjects, including 146 pregnancies in the conventional therapy group, during which treatment was temporarily changed, according to the study protocol.)

FIGURE 54-3. Measurement of glycosylated hemoglobin (HbA_{1c}) in DCCT patients with type 1 diabetes, assigned to intensive or conventional therapy. Median values are shown. Differences are statistically significant at all time points after baseline ($p < 0.001$). (Adapted with permission, the DCCT Research Group.⁷⁷)

The appearance and progression of retinopathy and other complications were assessed regularly. Retinopathy was assessed seven-field fundus photography performed every 6 months. Renal function was assessed by annual measurement of creatinine clearance and albumin excretion rate on timed 4-hour urine samples measured in the clinics. Neuropathy was evaluated by clinical examination (neurologic history and physical examination), electrophysiology (peripheral nerve conduction velocities), and autonomic nerve testing. The clinical and electrophysiologic evaluations were performed at baseline, at 5 years, and at study's end. The autonomic testing was done every 2 years.

The primary outcome in the DCCT was progression of diabetic retinopathy. Therefore, the DCCT had been planned to have statistical power to detect a 33.5% treatment effect for diabetic retinopathy. Many observers had hoped for at best a 40% reduction in event rates in the intensive therapy group versus the conventional therapy group. The results (Table 54-3) dramatically exceeded anyone's wildest expectations.⁸⁹ Cumulative 8.5-year rates of clinically important sustained progression of diabetic retinopathy (i.e., three or more steps change on the quantitative gradings scale sustained at two consecutive 6-month visits) were 54.1% with conventional treatment and 11.5% with intensive treatment in the primary prevention cohort and 49.2% with conventional treatment and 17.1% with intensive treatment in the secondary intervention cohort (Fig. 54-4). Thus retinopathy progression was significantly reduced by 70.3% in the combined cohorts, by 78.5% for those in the primary prevention cohort with no retinopathy at entry, and 64.5% for those in the secondary intervention cohort with no retinopathy at entry. The analysis over time suggested that the beneficial effects may actually be underestimated, since event rates increased substantially in the conventional treatment group over time, while changing relatively little in the intensive treatment group.

In the secondary intervention cohort, rates of progression of retinopathy to more severe events were also reduced significantly. Progression to severe nonproliferative retinopathy or worse was reduced by 60.8%. Progression to neovascularization was reduced by 46.3%. The frequency of clinically significant macular edema was reduced by 22.1%, but this did not achieve statistical significance. The need for laser photocoagulation, an index of progression of sight-threatening retinopathy, was significantly reduced by 56%

TABLE 54-3 DCCT Risk Reduction for Intensive Therapy (versus Conventional Therapy)

Event	Combined Cohorts	Primary Cohort	Secondary Cohort
<i>Diabetic retinopathy</i>			
Clinically important sustained progression	70.3%	78.5%	64.5%
1 yr duration diabetes prior to entry	92%		
5 yr duration diabetes prior to entry	77%		
10 yr duration diabetes prior to entry	64%		
15 yr duration diabetes prior to entry	53%		
Adolescents		53%	70%
Progression to severe nonproliferative retinopathy or worse			60.8%
Progression to neovascularization			46.3%
Clinically significant macular edema			22.1% NS*
Laser photocoagulation	56%		
Initial appearance of any retinopathy		27%	
<i>Diabetic nephropathy</i>			
Microalbuminuria AER† >28 µg/min	39%	34%	43%
Adolescents			55%
Sustained microalbuminuria	60%	56%	61%
"Advanced" microalbuminuria	51%	39%	56%
AER ≥70 µg/min			
Sustained "advanced" microalbuminuria	65%	54%	67%
"Clinical grade albuminuria"	54%	44% NS	56%
AER ≥208 µg/min			
Advanced nephropathy	NS		
AER ≥208 µg/min + C _{cr} ‡ < 70 mL/min / 1.73 m ² BSA§			
<i>Diabetic neuropathy</i>			
Incidence confirmed clinical neuropathy	64%	71%	61%
Prevalence clinical neuropathy	48%	54%	45%
Prevalence abnormal peripheral NCV¶	44%	59%	38%
Prevalence abnormal ANS#	53%	56%	51%
<i>Microvascular events</i>			
Cardiac and peripheral vascular events combined	41% (p = 0.06)		
Elevated LDL**cholesterol > 160 mg/dL	35%		

*NS = not significant.

†AER = albumin excretion rate.

‡C_{cr} = creatinine clearance.

§BSA = body surface area.

¶NCV = nerve conduction velocity.

#ANS = autonomic nervous system testing.

**LDL = low-density lipoprotein.

the combined cohorts. In addition, the initial appearance of any retinopathy (as opposed to clinically significant retinopathy) in the primary prevention cohort was significantly reduced by 27%.

The DCCT investigators noted that the slowing in progression of retinopathy was substantial in magnitude, increased with time, was consistent across all outcome measures assessed, and was present across the spectrum of retinopathy severity enrolled in the DCCT.

At the end of the DCCT, the patients in the conventional therapy group were offered intensive therapy, the care of all patients was transferred to their own physicians, and most were enrolled in the Epidemiology of Diabetes Interventions and Complications (EDIC) study, a long-term observational study.⁹⁰⁻⁹² Retinopathy was evaluated by fundus photography in 1208 patients during the fourth year after the DCCT ended, and nephropathy was evaluated on the basis of urine specimens obtained from 1302 patients during the third or fourth year, approximately half of whom were from each treatment group. The difference in the median HbA_{1c} values between the conventional therapy and intensive therapy groups during the DCCT (average, 9.1% and 7.2%, respectively) narrowed

during follow-up (median during the first 4 years of follow-up, 8.2% and 7.9%, respectively; $p < 0.001$),⁹¹ and by year 6, both groups had HbA_{1c} levels of 8.1%.⁹² Nevertheless, during 4.5 years of EDIC follow-up, a smaller proportion of patients in the intensive therapy group than in the conventional therapy group had worsening of retinopathy (76% adjusted odds reduction), progression to proliferative retinopathy (74% adjusted odds reduction), clinically significant macular edema (77% adjusted odds reduction) (all $p < 0.001$), and the need for laser therapy (77% adjusted odds reduction) ($p = 0.002$).⁹¹ The EDIC follow-up to DCCT demonstrates that the effects of any level of hyperglycemia increase exponentially over time and continue even after the differences between groups narrow. They suggest that intensive therapy offers a prolonged benefit in terms of reduction in the risk of complications.

Outcome measures related to diabetic nephropathy were also examined, and again dramatic improvements were observed,^{77,79} yet these effects were not evident in the first 3–5 years of the study. The incidence of microalbuminuria, a sign of early renal damage, defined as an albumin excretion rate (AER) greater than 28 µg/min (40 mg/24 h), was significantly reduced by 39% in the combined

FIGURE 54-4. Cumulative incidence in the DCCT of a sustained change in retinopathy (defined as a change in fundus photography of at least three grading scale steps from baseline that was sustained for at least 6 months) in patients with T1DM receiving intensive or conventional therapy in (A) the primary prevention cohort, and (B) the secondary intervention cohort. (Adapted with permission from the DCCT Research Group.⁷⁷)

cohorts, by 34% in the primary prevention cohort, and by 43% in the secondary intervention cohort (Fig. 54-5A). The incidence of sustained microalbuminuria (i.e., an AER $>28 \mu\text{g}/\text{min}$ on two consecutive annual evaluations) was significantly reduced by 60% in the combined cohorts, by 56% in the primary prevention cohort, and by 61% in the secondary intervention cohort. More severe “advanced” microalbuminuria (i.e., an AER $\geq 70 \mu\text{g}/\text{min}$ [$100 \text{ mg}/24 \text{ h}$]), which data from the Steno studies suggested is more predictive of evolution into clinical nephropathy,³³ was significantly reduced by 51% in the combined cohorts, by 39% in the primary prevention cohort, and by 56% in the secondary intervention cohort (Fig. 54-5B). The incidence of sustained “advanced” microalbuminuria with an AER $\geq 70 \mu\text{g}/\text{min}$ on two consecutive annual evaluations,

FIGURE 54-5. Cumulative incidence in the DCCT of a clinical nephropathy (urinary albumin excretion $\geq 300 \text{ mg}/24 \text{ h}$) (dashed lines) and microalbuminuria (urinary albumin excretion $\geq 40 \text{ mg}/24 \text{ h}$) (solid lines) in patients with T1DM receiving intensive or conventional therapy in (A) the primary prevention cohort, and (B) the secondary intervention cohort. (Subjects with baseline urinary albumin excretion $\geq 40 \text{ mg}/24 \text{ h}$ were excluded from the analysis of development of microalbuminuria). (Adapted with permission from the DCCT Research Group.⁷⁷)

was significantly reduced by 65% in the combined cohorts, by 54% in the primary prevention cohort, and by 67% in the secondary intervention cohort. Clinically significant renal damage, termed “clinical grade albuminuria” and defined as an AER $\geq 208 \mu\text{g}/\text{min}$ ($300 \text{ mg}/24 \text{ h}$), was significantly reduced by 54% in the combined cohorts. This event was mostly confined to the secondary intervention cohort, where the reduction was by 56% (both for initial and sustained appearance). In the primary prevention cohort, there was a 44% reduction, but the event rate was so low that this did not achieve statistical significance. Advanced nephropathy, defined as an AER $\geq 208 \mu\text{g}/\text{min}$ ($300 \text{ mg}/24 \text{ h}$) and a creatinine clearance below $70 \text{ mL}/\text{min}/1.73 \text{ m}^2$ body surface area, developed very rarely, involving only seven subjects, two in the intensive group

and five in the conventional group. In the secondary intervention cohort, after the first year, there was a 6.5%/y increase in AER in the conventional group in contrast to essentially no change (−0.3%/y) in the intensive group. Neither the rate of change of blood pressure nor the appearance of hypertension differed significantly between treatment groups.

During the EDIC follow-up of the DCCT, the proportion of patients with an increase in urinary albumin excretion was significantly lower in the intensive therapy group at both the 4.5- and 6-year time points.^{91,92} After 6 years of EDIC, 4.2% of those in the intensive therapy group had newly diagnosed microalbuminuria (during EDIC) versus 12.7% in the conventional therapy group (69% adjusted odds reduction of prevalent microalbuminuria; $p < 0.0001$). Likewise, after 6 years of EDIC, 0.6% were newly diagnosed with clinical albuminuria in the intensive therapy group versus 5.4% in the conventional therapy group (87% adjusted odds reduction; $p = 0.0022$).⁹²

Marked improvement in neuropathic outcomes was also seen, despite the fact that most of these were only assessed at baseline, at 5 years, and at study's end.^{77,80} (Autonomic nerve testing was done every 2 years.) Confirmed clinical neuropathy was defined as a history and/or physical examination consistent with clinical neuropathy confirmed by either abnormal peripheral nerve conduction or autonomic nerve testing. The incidence of such confirmed clinical neuropathy in the combined cohorts after 5 years of follow-up was 13% with conventional treatment and 5% with intensive treatment. This corresponded to a risk reduction of 64% in the combined cohorts, by 71% for those in the primary prevention cohort, and by 61% for those in the secondary intervention cohort. The prevalence of clinical neuropathy was reduced by 48% in the combined cohorts, by 54% in the primary prevention cohort, and by 45% in the secondary intervention cohort. The prevalence of abnormal peripheral nerve conduction was reduced by 44% in the combined cohorts, by 59% in the primary prevention cohort, and by 38% in the secondary intervention cohort. The prevalence of abnormal autonomic nerve testing was reduced by 53% in the combined cohorts, by 56% in the primary prevention cohort, and by 51% in the secondary intervention cohort. Nerve conduction velocities generally remained stable with intensive therapy, while declining significantly with conventional treatment. On cardiovascular autonomic testing, in the secondary intervention cohort, R-R variation was less abnormal with intensive treatment (7% abnormal at 4–6 years) than conventional treatment (14% abnormal; $p = 0.004$).⁸¹ No statistical difference was seen in the primary prevention cohort ($p = 0.17$), but the difference was significant in the combined cohorts (5% versus 9%; $p = 0.0017$). There were few abnormal Valsalva ratios or postural tests during the trial, and no differences between groups. However, both the R-R variation and the Valsalva ratio had significantly greater slopes of decline over time in the conventional treatment group than the intensive treatment group.

These beneficial effects of intensive therapy were not without associated risks. The chief adverse event associated with intensive therapy was a threefold increase in severe hypoglycemia,⁷⁷ defined as those episodes requiring assistance of another person to recover, confirming earlier DCCT reports.⁸² This included a threefold increased risk of coma or seizures consequent to hypoglycemia. Emergency room visits or hospitalization for hypoglycemia was increased 2.3-fold in the intensive therapy group. There were no deaths attributable to hypoglycemia among subjects in either treatment group, although a study patient was involved in a motor vehicle accident leading to the death of a nonstudy participant. Importantly,

53% of severe hypoglycemic episodes occurred during sleep, and 35% occurred without warning symptoms while awake. In the earlier report,⁸² it was noted that 23% of severe hypoglycemic episodes were associated with missed meals.

There was also increased weight gain among intensive treatment subjects.⁷⁷ This group had a 33% increased risk of becoming overweight, defined as 120% of ideal body weight. Average weight gain was 10.1 lb greater in the intensive group. With intensive treatment, subjects in the fourth quartile of weight gain had the highest body mass index (BMI), blood pressure, and levels of triglyceride, total cholesterol, low-density lipoprotein cholesterol (LDL-C), and apolipoprotein B compared with the other weight gain quartiles, with the greatest difference seen when compared with the first quartile.⁸³

Infections at sites of catheters used for continuous subcutaneous insulin infusion (CSII) occurred at a rate of 12 episodes per 100 patient-years of follow-up. Since CSII was only used in the intensive group, all of these infections were in those subjects.

Importantly, there was no difference in frequency of diabetic ketoacidosis between groups, both having an event rate of approximately two episodes per 100 patient-years of follow-up. Moreover, there was no difference between groups in neurobehavioral events, which might be indicative of brain insult consequent to hypoglycemia. Also, there was no difference between groups in psychological symptom scores or quality of life.

The DCCT examined whether the effects of intensive therapy could be demonstrated in the subset of adolescent subjects (13–17 years of age at entry) who participated in the trial.⁸⁴ There were 125 adolescent subjects in the primary prevention cohort, and 70 in the secondary intervention cohort. Intensive therapy effectively delayed the onset and slowed the progression of diabetic retinopathy and nephropathy when initiated in adolescent subjects. Among adolescents, intensive therapy decreased the risk of having retinopathy by 53% in the primary prevention cohort, and decreased the risk of retinopathy progression by 70% in the secondary intervention cohort. It also decreased the occurrence of microalbuminuria by 55% in the secondary intervention cohort. Motor and sensory nerve conduction velocities were faster in intensively treated adolescent subjects. As in the entire study sample, the major adverse event with intensive therapy was a nearly threefold increase of severe hypoglycemia.

Macrovascular events, both cardiac and peripheral vascular, were not significantly reduced in the primary analysis.⁸⁵ Yet the outcome, when episodes of cardiac and peripheral vascular events are combined, showed a 41% risk reduction, which was just short of being statistically significant ($p = 0.06$). Certainly there was no evidence, as was feared by some critics, of an increased rate of macrovascular events in the intensive treatment group. The risk of developing an elevated LDL cholesterol, defined as a value greater than 160 mg/dL, was significantly reduced by 35% overall. The risk of developing other lipid abnormalities was not significantly affected, yet the original DCCT analysis^{77,85} counted first events in any subject. In the context of a meta-analysis that considered the combined risk of all fatal and nonfatal macrovascular events (not just first events), the DCCT results showed risk reductions of 57% in the primary prevention cohort and 71% in the secondary intervention cohort, both of which were statistically significant.⁹³ Although in this analysis the results were driven by a relatively small number of DCCT patients with multiple events, taken together with the near statistical significance in the primary analysis, it is suggestive of a beneficial effect of intensive therapy on macrovascular complications.

In an analysis primarily focusing on the costs of implementation of intensive therapy, it was calculated that intensive therapy resulted in 15.3 years of living without complications and a gain of 5.1 years in life expectancy.⁸⁶

In subsequent analyses, the DCCT investigators examined the relationship of glycemic exposure to the risk of development and progression of diabetic complications.^{87,88} Using multiple regression analyses employing generalized estimating equations, and a number of regression models to assess risks, they found that total glycemic exposure was the dominant factor associated with risk of retinopathy progression (the principal DCCT outcome measure), with comparable results seen with other retinal outcome measures and with renal and neurologic outcome measures. Total glycemic exposure is defined as the baseline HbA_{1c} related to duration of diabetes prior to study entry, the mean study HbA_{1c} related to time in the study, and the interaction between these variables. This is demonstrated in Fig. 54-6, which shows the impact of treatment group and time on absolute risk of sustained retinopathy progression.⁸⁸ Within each treatment group, the mean HbA_{1c} during the trial was the dominant predictor of retinopathy progression (and the other outcome measures), with a continuous risk gradient without an apparent glycemic threshold. Figure 54-7⁸⁹ shows a stylized model of the kind of continuous risk gradients demonstrated by the DCCT results, in which the event rate for any outcome measure is set to "1" for an HbA_{1c} of 6%.

Risk increased with time in the study in the conventional treatment group but remained relatively constant in the intensive treatment group.⁸⁸ In addition, the initial level of HbA_{1c} at eligibility screening and the duration of diabetes at entry were identified as baseline variables that predicted risk of progression. The shorter the duration of disease, the greater the benefit seen. Nevertheless, substantial benefit still accrued regardless of duration of diabetes prior to entry. Whereas retinopathy progression was significantly reduced by 70.3% overall, the risk reduction was 92% for those with only 1 year of diabetes prior to entry, 77% for those with 5 years of diabetes prior to entry, 64% for those with 10 years of diabetes prior to entry, and 53% for those with 15 years of diabetes prior to entry.

Thus intensive therapy effectively delays the onset and slows the progression of diabetic retinopathy, diabetic nephropathy, and diabetic neuropathy in patients with T1DM. It results in increased life expectancy and a prolonged period free of complications.

FIGURE 54-6. Absolute risk of sustained retinopathy progression by years of follow-up and treatment group in the DCCT. With time, the curves diverge, suggesting that the beneficial effects of intensive therapy may be underestimated. (Adapted with permission from DCCT Research Group.⁸⁸).

FIGURE 54-7. Stylized relative risks for development of various complications as a function of mean HbA_{1c} during follow-up in the DCCT. For the purposes of illustration, the relative risk of various complications is set to 1 at HbA_{1c} of 6%. The lines depict a stylized relationship for risk of sustained progression of retinopathy (**diamonds**), progression to clinical nephropathy (urinary albumin excretion ≥ 300 mg/24 h) (**open circles**), progression to severe nonproliferative or proliferative retinopathy (**solid squares**), progression to clinical neuropathy (**solid triangles**), and progression to microalbuminuria (urinary albumin excretion ≥ 40 mg/24 h) (**open squares**). (Adapted with permission from Skyler.⁸⁹)

There may be beneficial effects on macrovascular disease, but these have yet to be convincingly demonstrated. The risks of intensive therapy are increased frequency of severe hypoglycemia and greater weight gain. The benefits more than outweigh the risks in most patients with T1DM. Therefore, intensive therapy, with the goal of achieving glucose levels as close to the nondiabetic range as possible, should be employed in most patients with T1DM.

Intervention Trials: Type 2 Diabetes

The Kumamoto Study

The Kumamoto Study was designed to be similar to the DCCT, except the subjects had T2DM.⁹⁴⁻⁹⁶ Thus the study contrasted intensive insulin therapy (multiple daily injections—preprandial regular and bedtime intermediate-acting insulin) and conventional insulin therapy (once or twice daily intermediate-acting insulin) in two cohorts—a primary prevention cohort and a secondary intervention cohort. A total of 110 thin Japanese patients with T2DM were randomized. Of these, 102 subjects completed the initial 6-year study,⁹⁴ with 99 subjects completing 8 years of follow-up,⁹⁵ and 97 subjects completing 10 years of follow-up.⁹⁶

Over the initial 6 years of follow-up, the glycemic outcomes and risk reductions were almost identical to those found in the DCCT. In the experimental group with intensive treatment, mean glycosylated hemoglobin (HbA_{1c}; upper limit of normal 6.4%) was reduced from 9.0% to 7.1% versus no change in the control group with standard treatment—9.2% to 9.4% ($p < 0.001$).⁹⁴ The 8-year mean HbA_{1c} was similar to that at 6 years—7.2% in the intensive group and 9.4% in the conventional group.⁹⁵ The mean blood glucose (over 6 years) was 157 mg/dL in the intensive group and 221 mg/dL in the conventional group, similar to that seen in the DCCT. Likewise, there were significant differences between groups in fasting blood glucose, mean amplitude of glycemic excursions (MAGE), and M value (an index of lability of glycemia).

The 6-year risk reduction⁹⁴ for two-step progression of diabetic retinopathy overall was 65% by crude relative risk analysis

and 69% by proportional hazards analysis. The risk reduction was 76% for those in the primary prevention cohort, and 65% for those in the secondary intervention cohort. In addition, in the secondary intervention cohort, progression of retinopathy to proliferative or severe nonproliferative retinopathy was reduced by 40%, and the need for laser photocoagulation also was reduced by 40%. By 10 years, crude relative risk reductions for the combined cohorts were 67% for retinopathy progression, 69% for progression of retinopathy to proliferative or severe nonproliferative retinopathy, and 77% for photocoagulation.⁹⁶

Nephropathy was divided into three stages depending on urinary albumin excretion—normoalbuminuria (<30 mg/24 h), microalbuminuria (30–300 mg/24 h), or clinical grade albuminuria (>300 mg/24 h). Overall risk of nephropathy progression was reduced by 70%—microalbuminuria by 57%, and albuminuria by 100% (a statistical anomaly because no clinical-grade albuminuria appeared in the intensive group).⁹⁴ By 10 years, overall crude relative risk reduction for nephropathy progression in the combined cohorts was 66%.⁹⁶

Motor and sensory nerve conduction velocities and vibration thresholds were better in the intensive group than the conventional group at 6 years and 8 years.^{94,95} By 10 years, overall crude relative risk reduction for clinical neuropathy in the combined cohorts was 64%.⁹⁶

Macrovascular events—combined cardiac, cerebrovascular, and peripheral vascular events—were said to be reduced by 54% in the original report,⁹⁴ but the total number of events was very low. By 10 years, the 95% confidence interval (2–78%) for overall crude relative risk reduction for reduction of macrovascular events in the combined cohorts became significant, with a nominal risk reduction of 54%.⁹⁶ Diabetes-related deaths over 10 years were reduced by 81%.⁹⁶

In contrast to the DCCT, hypoglycemia was not a problem. Over the entire study period, six patients in the intensive group and four patients in the conventional group had one or more episodes of mild hypoglycemia, while no patient had seizure, coma, or severe hypoglycemia requiring the assistance of another person. Likewise, weight gain was not a major problem. There was a slight but not significant increase in BMI in both groups from baseline to 6 years.

Thus in this randomized controlled study designed to examine the influence of glycemic control on diabetic complications in T2DM, intensive therapy was found to delay the onset and the progression of early stages of retinopathy, nephropathy, and neuropathy, and to decrease the frequency of macrovascular events.

The United Kingdom Prospective Diabetes Study (UKPDS)

The United Kingdom Prospective Diabetes Study (UKPDS), a randomized, multicenter controlled clinical trial, demonstrated that an intensive treatment policy in T2DM, with the goal of meticulous glycemic control, could decrease clinical diabetic complications.^{97–102} The UKPDS was conducted in 23 centers. Enrollment was between 1977 and 1991, and end-of-study evaluations were performed during 1997. UKPDS screened 7616 newly diagnosed patients who had the clinical phenotype of T2DM.^{97,98} Of these, 5102 were recruited and completed a 3-month vigorous dietary treatment run-in period. Of these, 744 continued to manifest symptoms and/or had fasting plasma glucose (FPG) greater than 270 mg/dL and were excluded from the main treatment protocol. Another group attained FPG less than or equal to 108 mg/dL and were initially excluded from randomization, but could be randomized

later if their subsequent FPG exceeded 108 mg/dL, with the exception of 149 individuals who were either lost or never reached the 108 mg/dL threshold. Thus a total of 4209 individuals with newly diagnosed T2DM were randomized in the main protocol. At entry, they were 25–63 years of age (median 53 years).

Subjects were randomly assigned either to “intensive treatment policy” (originally called “active treatment policy”) or “conventional treatment policy.” Intensive policy aimed at achieving fasting plasma glucose of 108 mg/dL using various pharmacologic agents. Conventional policy attempted control with diet alone, adding pharmacologic therapy when symptoms developed or fasting plasma glucose exceeded 270 mg/dL. The randomization was not balanced, as there were several arms in the intervention group. These included insulin, sulfonylureas, and among obese patients, metformin, but it was a bit more complicated than that. In the first 15 (of the 23) centers, the sulfonylureas were either glyburide (glibenclamide) or chlorpropamide, and it was only in these 15 centers that obese patients could receive metformin. In the last eight centers, the sulfonylureas were either glipizide or chlorpropamide. Moreover, in these eight centers the protocol was different and involved early addition of insulin if FPG could not be maintained lower than 108 mg/dL. It is important to note that therapeutic additions (in contrast to dose titrations) could not otherwise be made unless FPG reached 270 mg/dL, with the exception of some subgroups to be discussed later.

The primary outcome measures in the UKPDS were three aggregate end-points—“any diabetes-related endpoint” (sudden death, death from hyperglycemia or hypoglycemia, myocardial infarction, angina, heart failure, stroke, renal failure, amputation, vitreous hemorrhage, retinopathy requiring photocoagulation, blindness in one eye, or cataract extraction), “diabetes-related death” (death from myocardial infarction, stroke, peripheral vascular disease, renal disease, hyperglycemia or hypoglycemia, and sudden death), and all-cause mortality.^{97,99} Multiple other individual clinical and surrogate subclinical end-points were also assessed. Additional clinical end-point aggregates were used: myocardial infarction (fatal and nonfatal) and sudden death, stroke (fatal and nonfatal), amputation or death due to peripheral vascular disease, and microvascular complications (retinopathy requiring photocoagulation, vitreous hemorrhage, and renal failure).

The primary analysis was based on the “intention to treat” principle—comparing subjects assigned “intensive policy” or “conventional policy.”⁹⁹ Inexplicably, those obese subjects randomized to metformin were not included in the primary “intention to treat” analysis. Since these subjects were randomized with the other subjects,⁹⁷ there appears to be no reason for them to have been excluded from analysis. Although the investigators claim they never intended to include them in the primary analysis, that might be inappropriate, since a major aspect of the “intention to treat” principle is to include all subjects randomized.

Secondary analyses of the effects of individual treatments also were reported. In one paper, the results of treatment with glyburide, chlorpropamide, or insulin among subjects in the first 15 centers were compared.⁹⁹ In a second paper, the results of treatment with metformin among obese subjects in the first 15 centers also were considered.¹⁰⁰

The intensive policy group achieved a median HbA_{1c} of 7.0% versus 7.9% in the conventional policy group ($p < 0.001$) (Fig. 54-8).⁹⁹ Initially, with vigorous dietary therapy during the 3-month run-in period, there was a dramatic reduction of HbA_{1c}, from ~9.0% to 7.08%, accompanied by a weight loss of ~5 kg (~11

FIGURE 54-8. Measurement of glycosylated hemoglobin (HbA_{1c}) in UKPDS patients with T2DM assigned to intensive treatment policy or to conventional treatment policy. Median values are shown. Differences over the course of the study are statistically significant ($p < 0.0001$). (Adapted with permission from UKPDS Group.⁹⁹)

lb).⁹⁸ Over the first few years, the intensive policy group achieved HbA_{1c} levels in the 6% range, while the conventional policy group maintained HbA_{1c} levels in the 7% range. Subsequently, there was a progressive deterioration in glycemia over time. Nevertheless, approximately the same degree of glycemic separation was maintained for 6–20 years, with a median duration of follow-up of 11.1 years.

As noted, the primary outcome measures in the UKPDS were three aggregate end-points—“any diabetes-related endpoint,” “diabetes-related death,” and all-cause mortality. Of these, only any diabetes-related endpoint was significantly impacted—a 12% risk reduction.⁹⁹ In addition, risk reductions were seen for other end-points. Patients assigned intensive policy had a significant 25% risk reduction in microvascular end-points compared with conventional policy ($p < 0.01$), most of which was due to fewer cases of retinal photocoagulation, for which there was a 29% risk reduction ($p < 0.005$).⁹⁹ There was also a decreased risk of cataract extraction (24% risk reduction), deterioration in retinopathy (21% risk reduction at 12 years’ follow-up), and of microalbuminuria (33% risk reduction at 12 years’ follow-up).⁹⁹

The only macrovascular end-point that demonstrated a trend in risk reduction in the main analysis was myocardial infarction (16% risk reduction), which did not quite reach statistical significance ($p = 0.052$).⁹⁹ In the metformin subgroup analysis within UKPDS, however, there were significant risk reductions in diabetes-related deaths (42% risk reduction, $p = 0.017$), any diabetes-related endpoint (32% risk reduction, $p = 0.0023$), and myocardial infarction (39% risk reduction, $p = 0.01$).¹⁰⁰ In the metformin subgroup, a combined analysis of all macrovascular end-points (myocardial infarction, sudden death, angina, stroke, peripheral vascular disease) showed a risk reduction of 30% over the conventional therapy group ($p = 0.02$).¹⁰⁰ Had the metformin subjects not been excluded from the primary analysis, the overall risk reduction for myocardial infarction would have been 18%, and likely would have achieved statistical significance.

In analyzing the individual therapies, the major difference was the increased risk reduction for macrovascular disease seen in the relatively small obese subgroup treated with metformin.¹⁰⁰ There was an even smaller subgroup in which metformin was added early to sulfonylurea-treated patients in a randomized design.¹⁰⁰ In this subgroup, there was an inexplicable difference in outcome, particularly diabetes-related deaths, which were higher in the combined

metformin-sulfonylurea group than those who continued on sulfonylureas alone. A subsequent analysis suggested that the expected death rate was higher than that observed in either group, although the sulfonylurea group had a statistically significantly lower rate than either that expected or that seen in the metformin-sulfonylurea combination group.¹⁰¹ With sulfonylurea therapy, there was no evidence of deleterious effect on myocardial infarction, sudden death, or diabetes-related deaths.⁹⁹ With insulin therapy, there was no evidence for more atheroma-related disease.⁹⁹ Thus in UKPDS, there was no evidence of an adverse effect of insulin or insulin secretagogues on macrovascular disease, thus negating the erroneous (but widely held) belief that increasing insulin availability may in some way be detrimental to patients with diabetes.

The overall risk reductions found in the UKPDS are shown in Table 54-4.

In a subsequent analysis, performed across all UKPDS subjects, the relationship between exposure to glycemia over time and the risk of macrovascular or microvascular complications was determined.¹⁰² The incidence of clinical complications was significantly associated with glycemia. Each 1% reduction in updated mean HbA_{1c} was associated with reductions in risk of 21% for any end-point related to diabetes ($p < 0.0001$), 21% for deaths related to diabetes ($p < 0.0001$), 14% for myocardial infarction ($p < 0.0001$), 43% for peripheral vascular disease ($p < 0.0001$), and 37% for microvascular complications ($p < 0.0001$). No threshold of risk was observed for any end-point. Figure 54-9 depicts the relationship between updated mean HbA_{1c} (glycemic exposure) and incidence of microvascular disease and myocardial infarction.¹⁰²

Thus the UKPDS provides substantial evidence that glycemic control impacts also on T2DM. The continuous relationship of glycemic exposure to risk of complications, without a threshold,¹⁰² is similar to that seen in T1DM in the DCCT.^{87,88} Taken together, these findings suggest that the target for glycemic control should be an HbA_{1c} level as close to normal as feasible.

POST-TRANSPLANTATION STUDIES

Histologic studies on biopsy specimens of transplanted kidneys permit study of the influence on renal structure of the metabolic milieu in which the kidney exists. The University of Minnesota Transplantation Program has provided much of the available data. These human observations, although confined to a few individuals,

TABLE 54-4 UKPDS Risk Reduction for Intensive Therapy (versus Conventional Therapy)

Event	Main Analysis	Metformin Subgroup
Any diabetes-related end-point	12%	32%
Diabetes-related deaths	NS	42%
All-cause mortality	NS	36%
Myocardial infarction	16% ($p = 0.052$)	39%
Microvascular end-points	25%	NS
Fatal myocardial infarction	NS	50%
Laser photocoagulation	29%	NS
Cataract extraction	24%	NS
Retinopathy at 12 years	21%	NS
Microalbuminuria at 12 years	33%	NS

Percentage risk reduction for various UKPDS outcome measures in main analysis and in Metformin Subgroup.

NS = not significant.

FIGURE 54-9. UKPDS epidemiologic analysis depicting the relationship between updated mean HbA_{1c} (glycemic exposure) and incidence of microvascular disease (circles) and of myocardial infarction (diamonds). (Adapted with permission from Stratton et al.¹⁰²)

provide further powerful and persuasive evidence about the relationship between glycemic control and evolution of diabetic complications. Only one randomized intervention study examined renal histology,⁴⁸ and it is consistent with a wealth of similar animal data which demonstrate that the metabolic milieu in which the kidney exists influences its histologic structure. In a hyperglycemic milieu, histologic features of diabetic nephropathy unfold. In a normoglycemic metabolic milieu, histologic changes do not appear and existing changes regress. The studies are summarized below.

Kidneys from Nondiabetic Donors in Diabetic Recipients

Michael Mauer, David Sutherland, and their coworkers in Minnesota have demonstrated that typical diabetic histologic changes, both glomerular changes and immunohistologic changes specific for diabetes, invariably develop in normal kidneys transplanted into patients with diabetes, usually within 2 years of transplantation.^{103–105} Comparable changes are not seen in kidneys transplanted into nondiabetic individuals.

Kidneys in Pancreas Transplant Recipients

In a series from the University of Minnesota, successful pancreas transplantation which normalized glycemia resulted in significantly less severe diabetic glomerulopathy in the transplanted kidneys of 12 diabetic patients than was seen in 13 matched diabetic patients who received renal allografts but did not have a pancreas transplant.¹⁰⁵ A recent larger confirmatory report from the Stockholm group reports similar findings in 20 diabetic patients after successful combined pancreatic and renal transplantation compared to 30 diabetic recipients after kidney transplantation only.¹⁰⁶ These series were heralded by an early report from Gliedman and colleagues,¹⁰⁷ who in a single patient noted that renal histology remained normal 4 years after combined renal and pancreatic transplantation. In addition, Bohman and associates have described a similar experience in two cases.¹⁰⁸ The Minnesota group also noted that pancreas transplantation results in regression of recurrent early diabetic nephropathy present at the time of pancreas transplantation.^{105,109}

Interestingly, in their first report, the Minnesota group noted a failure to see regression of more advanced lesions of diabetic nephropathy in the native kidneys 5 years after having had a pancreas transplant in patients who had not received kidney grafts.^{110,111} However, after 10 years, thickness of the glomerular and tubular basement membranes had decreased in comparison to baseline values.¹¹¹ Moreover, mesangial fractional volume (the proportion of the glomerulus occupied by the mesangium) had decreased at 10 years, mostly because of a reduction in mesangial matrix.¹¹¹

It should be noted that in contrast to the beneficial effects of pancreas transplantation on renal histology, no effects are seen on retinopathy.^{112,113} However, it should be noted that most pancreas transplant recipients have had such advanced retinopathy that they may be beyond the stage of measurable impact.

Kidneys from Diabetic Donors in Nondiabetic Recipients

George Abouna and coworkers from Kuwait have reported dramatic changes in kidneys taken from a diabetic donor and transplanted into two nondiabetic recipients.^{114,115} At the time of transplantation, the kidneys showed some histologic features of diabetic nephropathy, although Mauer has cautioned that the histologic changes demonstrated by Abouna and associates are not the lesions most representative of diabetic nephropathy.¹¹⁶ The renal changes in the donated organs had reversed on biopsies taken 7 months post-transplant, during which both recipients remained euglycemic.¹¹⁴ Fifteen months after transplant, one of the recipients developed steroid-induced hyperglycemia, and required initiation of insulin therapy. Twelve months later, he developed clinical evidence of renal disease, and on rebiopsy 30 months after transplant, the kidney showed recurrence of diabetic nephropathy.¹¹⁵

CONCLUSIONS

There is no doubt that hyperglycemia is essential to the development of diabetic microangiopathy. Multiple randomized controlled intervention studies have convincingly demonstrated that. In particular, the overall results reported by the DCCT dramatically exceeded all expectations. The benefits of intensive therapy include a slowing of the onset and progression of diabetic retinopathy, diabetic nephropathy, and diabetic neuropathy. The risks of intensive therapy are increased frequency of severe hypoglycemia and greater weight gain. These risks clearly must be considered whenever intensive therapy is contemplated. However, although in the DCCT there was a threefold increased risk for hypoglycemia in the intensive therapy group, for coma or seizure this amounts to one episode every 6.25 patient-years of follow-up, versus one episode every 20 patient-years of follow-up in the conventional treatment group. This may very well be tolerable. Thus the benefits of intensive therapy would seem to be worth the risks in most patients with T1DM. Therefore, intensive therapy, with the goal of achieving glucose levels as close to the nondiabetic range as possible, should be the standard management approach in most patients with T1DM.

The analyses from the Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR) and similar epidemiologic studies show that the relationship between glycemia and diabetic complications is present in both type 1 and type 2 diabetes. The results of

the UKPDS and the Kumamoto Study suggest that meticulous glycemic control also should be the therapeutic goal in T2DM. However, since the major morbidity and mortality in T2DM is a consequence of accelerated atherosclerosis, which is multifactorial in nature and not merely related to prevailing glycemia, attention also needs to be paid to other risk factors, such as high blood pressure, an excess of lipids, and cigarette smoking.

There is also a general relationship between degree of hyperglycemia as manifested by mean level of HbA_{1c} (or glycemia-years, analogous to pack-years of smoking) and the frequency, severity, and progression of microangiopathy. In both the UKPDS and the DCCT, the relationship between glycemic exposure and risk of development of complications was evident across the range of HbA_{1c} and without evidence of a threshold.^{87,88,102} In UKPDS, when subjects were examined by HbA_{1c} category, there was a log-linear relationship between HbA_{1c} and risk of complications, without evidence of a threshold.¹⁰² In the DCCT, where the relationship was examined continuously rather than categorically, an exponential relationship was seen between HbA_{1c} and risk of complications,^{87,88} again without evidence of a threshold.⁸⁸ This supports the view that the lower the glycemic exposure, the lower the risk of complications. However, the quantitation of the relationship between hyperglycemia and microangiopathy in an individual patient may be influenced by other factors, including coexisting hypertension and genetic predisposition. Thus some individuals may be more genetically prone to microangiopathy, and so may develop these complications in the face of little hyperglycemia, while others with less genetic predisposition may escape complications in spite of substantial hyperglycemia. Nevertheless, it would appear that in most cases, regardless of a person's genetic substrate, the degree of hyperglycemia directly influences the risk of microangiopathy.

The evidence that glycemic control makes a difference in diabetic complications should serve to refocus the debate not only on the best means of attaining effective glycemic control, but also on the therapeutic targets that should be sought. Ironically, as noted by Robert Tattersall in his lucid historical review, "The Quest for Normoglycemia," the goal articulated by the DCCT investigators of maintaining glycemic status as close to normal as safely possible is identical to that recommended in 1923, shortly after the discovery of insulin.¹¹⁷

It should be noted, however, that no available intervention, save the drastic approach of pancreas transplantation, uniformly permits normalization of glycemia. All of the cited intervention studies achieved statistically significant glycemic separation between groups; none achieved normoglycemia. If normoglycemia is necessary to completely prevent, delay, or slow microangiopathy, then we cannot expect to totally prevent microangiopathy. However, because there is a continuous relationship between prevailing glycemia and risk of progression of complications, any improvement in glycemic control is beneficial. Therefore, a prudent clinical approach is to select treatment goals and treatment strategies that are individualized for each patient and that are designed to achieve the best control reasonably attainable in that patient, without adding unnecessary risk. In striving for meticulous control, we should therefore focus on those patients with longest life expectancy, while being slightly less aggressive in those with increased risk factors for devastating problems consequent to hypoglycemia. Meanwhile, we should expend our best efforts in devising and implementing newer therapeutic strategies that will more closely approximate metabolic normality. When that is ac-

complished, we have the potential of eliminating the microangiopathic complications of diabetes mellitus.

Pancreas Transplantation

David E. R. Sutherland

S. Michael Mauer

Angelika C. Gruessner

INTRODUCTION

β -Cell (beta cell) replacement by transplantation of a pancreas either as an immediately vascularized organ or as a free graft of isolated islets is the only treatment of type I diabetes mellitus (T1DM) that can make an afflicted individual independent of exogenous insulin (termed insulin independence). Pancreas transplantation has been able to consistently do so in a large number of patients at many centers throughout the world for more than a decade.¹

Historically, islet transplantation has been less successful for a variety of reasons,² but the gap is narrowing. Recently one center reported achieving insulin independence in several consecutive diabetic recipients by sequential grafting of islets obtained from more than one donor and using a relatively nondiabetogenic steroid-free immunosuppressive regimen.³ Another center reported achieving insulin independence in a few patients following transplantation of islets obtained from one donor per recipient.⁴

In the latter series at the University of Minnesota,⁴ the recipients had a low body mass index (BMI), while the donors had a high BMI. Thus the number of islets transplanted per unit weight in the Minnesota recipients from one donor was similar to that using multiple donors in the other series at the University of Alberta.³ These series show that pancreatic islet transplantation could eventually supersede vascularized pancreas transplantation as the means for β cell replacement therapy for the majority of diabetic candidates, but the transition will not be complete until islet transplantation mimics the efficiency of pancreas transplantation. One pancreas graft usually suffices to induce insulin independence regardless of the recipient's exogenous regimens. In addition, only a few centers currently possess the infrastructure to do islet isolation on a large scale, while pancreas transplants can be done at most centers with the logistics and infrastructure already developed for solid organ transplantation in general. In the interim, an integrated approach may be possible by selecting low-BMI diabetics for islet transplantation and using high-BMI donors for this population, while high-BMI diabetics receive pancreas grafts from low-BMI donors.

This chapter focuses on pancreas transplantation as an immediately vascularized graft. The rationale and objectives are the same as for islet transplantation. For candidates in whom islet transplantation can replace pancreas transplantation, the main benefit will be in elimination of the surgical complications that are as-

sociated with the latter. Currently, both approaches require generalized immunosuppression to prevent rejection. Strategies to induce specific immunologic tolerance are just beginning to be tested in the clinical arena. Nevertheless, advances in pharmacologic immunosuppression and infection prophylaxis have made organ transplantation in general increasingly successful and benign, and thus pancreas (or islet) transplantation will be applied to the extent that organs are available until strategies to prevent or actually treat the pathogenesis of diabetes materialize (for example, preventing autoimmunity before onset in T1DM, or if after onset, coupling such prevention with stimulation of β -cell regeneration⁵).

RATIONALE

The purpose of pancreas (or islet) transplantation is to establish euglycemia and free the diabetic patient of the daily burden of multiple insulin injections or dose or diet adjustments based on multiple fingerstick blood glucose determinations. This burden has to be assumed not only to remain alive (for T1DM) but also to lower the risk for secondary diabetic complications.

The Diabetes Control and Complications Trial (DCCT) conclusively proved that vigorous diabetic control reduces the incidence of secondary complications.⁶ The price is the rigorous discipline required to lower glycohemoglobin as much toward normal as possible, plus an increased frequency of insulin reactions and hypoglycemic episodes.⁷ Even in the DCCT group given intensive insulin treatment, mean glycosylated hemoglobin levels were a gram percent above normal. Some individuals developed secondary complications even when glycosylated hemoglobin levels were only moderately elevated. The incidence of secondary complications decreases progressively with decreasing mean glycosylated hemoglobin levels, but the threshold for zero risk is a constant normal value, something that currently can only be achieved with pancreas transplantation. A closed-loop insulin pump coupled to a glucose sensor should theoretically do the same, but a miniaturized, implantable, practical device is not yet available.

Thus at the moment, perfect diabetic control is only provided by β -cell replacement. The main current drawback of both pancreas and islet transplantation is the need to immunosuppress the recipient, but this can be done with oral drugs without the need for

constant dose adjustments. A pancreas transplant requires major surgery, but a successful graft makes the recipient euglycemic and glycosylated hemoglobin levels are normal for as long as the graft functions.^{8,9} The need for immunosuppression is only a relative drawback, since it is used for other organ transplants even when alternative treatments are available, such as dialysis for renal failure. Indeed, the modern management of diabetes by exogenous insulin may be as burdensome as dialysis is for renal failure: >4 blood glucose determinations daily and 4 insulin injections or a constantly placed needle adds up to 35–50 needle sticks per week, or approximately 2000 per year (dialysis 3 times per week with 2 needles is only 300 needle sticks per year). If one looks at exogenous insulin needle-intensive treatment as akin to dialysis, immunosuppression for treatment of diabetes by islet or pancreas transplantation is logical.

β -Cell transplants should ideally be performed before complications occur. Because of uncertainty in an individual patient as to whether he or she is complication-prone (even with poor control, not all get complications), as well as the uncertainty over what the individual side effects of immunosuppression will be, only a few institutions do pancreas transplants soon after onset of disease.¹⁰ Antirejection strategies to decrease the side effects of immunosuppression, however, are increasingly available.¹¹

During the past decade, pancreas transplants alone were largely employed in patients with very labile diabetes and hypoglycemic unawareness, a syndrome that may emerge many years after onset of diabetes, particularly in patients with neuropathy.¹² In this situation pancreas transplantation is the most effective treatment since it completely obviates insulin reactions. However, for patients who are not labile, but who wish to obviate a lifetime need for insulin injections and glucose monitoring, as well as to absolutely eliminate the risk of secondary diabetic complications by choosing the alternative risk of immunosuppression complications, pancreas transplantation can reasonably be chosen. To fully assess the trade-off and risks of immunosuppression versus the risks of secondary diabetic complications, randomization of candidates, transplantation versus insulin, soon after onset of diabetes would be ideal, but until that is done, a diabetic individual can just as logically choose one approach or the other. Even with emphasis on tight control through intensive glucose monitoring and constant insulin dose adjustments, the diabetes literature continues to show an extremely high rate of secondary complications that are just as morbid,¹³ if not more morbid, than those described secondary to chronic immunosuppression in organ allograft recipients.^{14,15}

Nevertheless, because of the need for immunosuppression, most pancreas transplants have been done either simultaneous with or subsequent to a kidney transplant in diabetic patients with advanced nephropathy.¹⁶ Nearly everyone agrees that a kidney transplant is preferable to dialysis in the treatment of uremia (particularly in diabetic patients). Thus when a diabetic patient is already obligated to immunosuppression, there is very little reason not to add a β -cell transplant, and only the surgical risks need to be considered. Indeed, simultaneous pancreas-kidney (SPK) transplants have even been done in insulin-treated uremic diabetics meeting criteria for type 2 diabetes mellitus (T2DM).¹⁷

Unfortunately, in uremic diabetic patients, retinopathy and neuropathy are usually far advanced and the DCCT did not study the effect of maintaining strict control on established lesions. Thus the main value of adding a pancreas to the kidney is the additional improvement of quality of life that accompanies being insulin-independent as well as dialysis-free.¹⁸ This is not to say that there

is no effect of the pancreas transplant on nonrenal secondary complications that are present in the uremic diabetic. Improvement in neuropathy has been documented.^{19–21} As expected, recurrence of diabetic nephropathy in a renal transplant is also prevented by successful pancreas transplant.^{22,23} Nevertheless, advanced retinopathy and vascular disease are unlikely to be affected,²⁴ even though a pancreas transplant has been shown to decrease atherosclerotic risk factors and improve endothelial function.²⁵ It is for this reason that early β -cell replacement should be the goal.

HISTORY

The first clinical pancreas transplant was performed at the University of Minnesota in 1966.²⁶ During the 1970s a few institutions performed a few cases with low success rates.²⁷ In 1980, the International Pancreas Transplant Registry (IPTR) was formed,²⁸ followed by annual reports.¹ By 2000 more than 15,000 pancreas transplants had been reported worldwide (Fig. 55-1), including more than 11,000 in the U.S.²⁹

A dramatic improvement in outcome occurred in the 1980s following advances in surgical techniques and the introduction of cyclosporine for immunosuppression. In the United States, the inception of the United Network for Organ Sharing (UNOS) in 1987, facilitating organ procurement and placement, was followed by a steady growth in the number of applicants. By the mid-1990s, more than 1000 pancreas transplants were being done yearly in the U.S.¹

SPK transplants have predominated in the past, but there is great potential for growth in the solitary β -cell transplant categories since far more cadaver (CAD) organs are available than are being transplanted. There are approximately 5500 CAD donors annually in the U.S., but many cannot be used for an SPK transplant since the majority of renal allograft candidates are nondiabetic. A large number of diabetic renal allograft recipients are available as candidates for pancreas (or islet) transplants after kidney (PAK) transplantation.³⁰ Likewise, the number of diabetic patients not in need of a kidney transplant in whom immunosuppression would be acceptable to become insulin-independent by a pancreas transplant alone (PTA) or islet transplant greatly exceeds the number of organs available. All should be used.

The historical development of pancreas transplantation has been summarized in detail elsewhere.³¹ In brief, the focus during the early years was on refinement of surgical techniques and reduction of surgical complications (many related to the exocrine pancreas), using either a segment (tail) of the pancreas or the entire

FIGURE 55-1. Number of pancreas transplants tabulated by the International Pancreas Transplant Registry (IPTR) from 1966 through 2000.

pancreas with attached duodenum. By the mid 1970s three techniques were in use: enteric drainage (ED) (first used by Richard Lillihei in 1967 at the University of Minnesota in Minneapolis), urinary drainage (first into the ureter by Marvin Gliedman at Montefiore Hospital in New York in 1970, and later modified by direct implantation into the bladder by Hans Solligner at the University of Wisconsin in 1982), and duct injection (first used by Jean-Michel Dubernard at Herriot Hospital in Lyon, France in 1974).

During the 1980s bladder drainage (BD) was shown to be safe,³² and it became the predominant technique in all recipient categories (Fig. 55-2). Some groups, however, continued to use ED,³³ and during the 1990s a shift back to ED occurred for SPK transplants (Fig. 55-3). In SPK recipients, the creatinine level can be used to monitor for kidney rejection, a surrogate marker for pancreas rejection when both organs come from the same donor. For solitary pancreas transplant (PTA or PAK), BD continues to be recommended because of the ability to monitor urine amylase, the most sensitive marker of pancreas rejection alone.³⁴

Vascularized management of the pancreas graft has also evolved. Drainage of the graft venous effluent can either be into the systemic or the portal circulation. Portal drainage was used for segmental pancreas grafts in a few patients by four groups in the 1980s.³⁵⁻³⁸ Portal drainage using whole pancreaticoduodenal grafts began in the 1990s, first coupled with bladder drainage,³⁹ and then with enteric drainage.^{40,41} Rosenlof and colleagues⁴⁰ described anastomosis to the recipient splenic vein and Gaber and associates⁴² to the recipient superior mesenteric vein (Fig. 55-4). Several groups adapted portal-enteric drainage as their routine or did prospective studies.⁴³⁻⁴⁵ It is more physiological than systemic drainage,⁴³ and

FIGURE 55-3. Enteric-drained (ED) simultaneous pancreas-kidney (SPK) transplant from a cadaver donor with systemic venous drainage.

possibly lowers the incidence of rejection,⁴⁶ although not all confirm that claim.⁴⁷ About 20% of SPK transplants in the United States have been portal-enteric drained since 1996.¹

Although segmental grafts were commonly used for pancreas transplants done in the 1970s, during the 1980s techniques for

FIGURE 55-2. Bladder-drained pancreaticoduodenal transplant alone (PTA) from a cadaver donor.

FIGURE 55-4. Enteric-drained SPK transplants with portal venous drainage of the pancreas graft via the superior mesenteric vein.

preserving the vascular supply to both the whole pancreas and the liver were developed.^{49,50} Thus nearly all groups now use pancreaticoduodenal grafts from CAD donors.⁵¹ Segmental grafts continue to be done, but primarily for pancreata procured from living donors.⁵² Pancreas transplants from living donors were first done at the University of Minnesota in 1979,⁵³ primarily as a solitary procedure at a time when the rejection rate for CAD grafts was high.⁵⁴ In the 1990s, living donor pancreas transplants were usually done simultaneously with a kidney (Fig. 55-5), in order to allow a single procedure, eliminate waiting time, and preempt dialysis for SPK recipients.⁵⁵⁻⁵⁷ Other institutions have also done living donor SPK transplants with good outcome.⁵⁸ The pressure to use living donor tissue primarily relates to long waiting times,⁵⁹ and once all CAD pancreata are being utilized, the number of applications for solitary pancreas transplants is likely to increase. Recently, the University of Minnesota has begun to do living donor segmental pancreatectomy laparoscopically, as has now become routine for living kidney transplantation.⁴⁸

Another option to shorten waiting time for the uremic diabetic and still perform a single operation is to do a simultaneous living donor kidney with a CAD pancreas transplant, first done in the 1980s,⁵⁴ and now applied much more frequently.⁶⁰ An interesting sidelight to the Minnesota living donor pancreas experience in the 1980s related to observations in diabetic recipients of segmental grafts from their nondiabetic identical twin donor counterparts. Without immunosuppression, isletitis recurred in the new graft.^{61,62} With immunosuppression, β -cell morphology and function were preserved in the identical twin donor graft.^{52,63} Thus for pancreas transplants in general to succeed in type 1 diabetic recipients, both rejection and autoimmune isletitis must be prevented. In regard to the latter, the generalized immunosuppressive regimens in use since at least the mid-1980s are adequate, since autoimmune recurrence in pancreas grafts is exceedingly rare,⁶⁴ except in the nonimmunosuppressed recipients.⁶³

In regard to immunosuppression, in the mid-1990s FK506 (tacrolimus) and mycophenolate mofetil became available, and were quickly applied to pancreas transplantation.^{65,66} These drugs have now become mainstays of immunosuppression in pancreas

FIGURE 55-5. Simultaneous segmental pancreas and kidney transplant from a living donor (LD). Either BD or ED can be used, but the BD technique has a lower complication rate and is illustrated. (Reproduced with permission from Gruessner et al.⁵⁶)

transplant recipients and have further improved results,^{67,68} particularly in solitary pancreas transplant recipients.^{69,70} Other recent additions to the immunosuppression regimens include sirolimus for maintenance and interleukin-2 receptor monoclonal antibody for induction, both yielding favorable results.⁷¹ Steroid withdrawal has also been shown to be associated with low rejection rates in stable pancreas transplant recipients.⁷²

Currently, there are more than 100 pancreas transplant programs in the United States.²⁹ Most have come into existence only during the past decade and are relatively small. A few centers have extensive experience.^{46,52,73,74} The University of Wisconsin has reported experience with more than 500 SPK transplants,⁷³ and the University of Minnesota has reported on a total of more than 1000 pancreas transplants.⁵² However, the overall recent results of pancreas transplantation are best viewed by compiling a review of the collective data.

In the following section the current results of pancreas transplants from CAD donors as tabulated by the IPTR are given. The results with living donor segmental pancreas transplants at the institution primarily using this approach are summarized in a separate section.

IPTR REPORT OF OUTCOME WITH CADAVER PANCREAS TRANSPLANTATION

Analyses of IPTR data have been published yearly since the mid-1980s, and the results (long-term insulin independence) have continually improved over time.¹ The latest Registry analyses²⁹ focus on U.S. cases done from 1996–2001, including >4500 SPK, >900 PAK, and >350 PTA cases (Fig. 55-6). The patient survival rates

FIGURE 55-6. Patient (A) and pancreas graft (B) survival rates from 1996–2001 U.S. cadaver SPK, PAK, and PTA transplants as reported to UNOS and the IPTR. (Reproduced with permission from Gruessner et al.²⁹)

are not significantly different between the three categories, and are >90% at 3 years posttransplant (Fig. 55-6A). Most deaths are from preexisting cardiovascular disease; the mortality risk of a pancreas transplant *per se* is extremely low (1-year patient survival for PTA recipients is 98%).

Pancreas graft survival rates were slightly higher in the SPK than the PAK and PTA categories, 84% versus 75% and 73%, respectively, at 1 year (Fig. 55-6B). The differences are in part due to the decreased ability to monitor for rejection episodes in enteric-drained solitary pancreas transplant recipients. In the SPK category, 1-year graft survival rates were 85% for BD ($n = 1781$) versus 83% for ED ($n = 2798$; $p = \text{ns}$). In the PAK category, the 1-year graft survival rates were 83% for BD ($n = 368$) versus 74% for ED ($n = 328$) cases ($p < 0.05$). In the PTA category, the 1-year graft survival rates were 81% for BD ($n = 190$) versus 73% for ED ($n = 133$) ($p < 0.05$). Thus with current immunosuppressive protocols (predominantly tacrolimus and mycophenolate mofetil for maintenance), 1-year graft survival rates of over 80% are achieved in all categories with bladder drainage, and in the SPK category with either bladder or enteric drainage.

Kidney graft survival rates in SPK recipients have been higher than for diabetic recipients of kidney transplants alone in all eras.⁷⁵ For the 1996–2001 SPK transplants, kidney graft survival rates were >90% at 1 year in both the ED and BD subcategories.

The proportion of older diabetic patients receiving pancreas transplants in the United States increased significantly during the 1990s. In 1988–1989, only 5% of the recipients were >45 years old. In 2000–2001, 75% were >45 years old in all three categories of recipients. Only 2% were <21 years old. The outcomes according to recipient age for 1997–2001 are shown in Figs. 55-7, 55-8, and 55-9. The age of the recipient has had very little impact on outcomes. In the SPK category, patient survival rates were over 90% at 1 year in both age categories (Fig. 55-7A), and 1-year graft survival rates were $\geq 80\%$ (Fig. 55-7B). In the PAK category, patient survival rates at 1 year were also >90% (Fig. 55-8A), and graft survival rates were again not significantly different (Fig. 55-8B). Interestingly, in the PTA category, the 1-year patient survival rate was 100% in the older age category (Fig. 55-9A), and the graft survival rates were significantly higher in the older PTA recipients, 85% versus 77% at 1 year (Fig. 55-9B). The young, nonuremic PTA recipients tend to have a higher rejection graft loss rate than the PAK and SPK recipients (at 2 years, 12% versus 5% and 3%, respectively). In the older group, the rejection graft loss rate at 2 years is low in all categories: 2%, 5%, and 3%, respectively.

With the increased number of older patients receiving pancreas transplants, it is not surprising that some have been classified as having T2DM. Most of the patients classified as type 2 have been in the SPK category. For 1996–2000 SPK transplants, 1-year insulin-independence rates were 84% in those classified as type 1 ($n = 3323$) and 83% in those classified as type 2 ($n = 157$).

The improvement in pancreas graft functional survival rates reflects a decrease in both the technical failure (TF) rate and rejection rates. The TF rate (grafts lost from thrombosis, pancreatitis, or perigraft infection) for 1997–2001 U.S. cases was 8% overall. In the analysis of technically successful cases (death with functioning graft censored), the 1-year rejection loss rate was only 2% for SPK, 6% for PAK, and 8% for PTA cases.

It is apparent that with the generalized immunosuppressive regimes being used currently, there is very little difference in pancreas graft survival rates in SPK and PAK recipients, giving further impetus to the use of living donor kidney in diabetic patients with

FIGURE 55-7. Patient (A) and pancreas graft (B) functional survival rates for 1997–2001 U.S. cadaver SPK transplants by recipient age.

advanced nephropathy. With a living donor kidney, the need for dialysis can be preempted and a subsequent pancreas transplantation from a CAD donor has nearly the same probability of success as that done simultaneously with a CAD kidney. The only drawback to a PAK is the need for two operations. For those with a suitable living donor, an SPK transplant with a segmental graft is an alternative to sequential transplants, as described in the next section.

LIVING SEGMENTAL DONOR PANCREAS TRANSPLANTS

Of the more than 15,000 pancreas transplants reported to the International Registry, slightly more than 1% have been from living donors (LDs).²⁹ As for other organ transplants, LDs are used to (1) alleviate the CAD donor shortage, (2) eliminate waiting time, and (3) decrease rejection.

The number of diabetics who would benefit from a pancreas transplant alone (PTA) exceeds the number of CAD donors. The number of nonuremic candidates registered has been well below the potential number of organs available, so waiting times have been relatively short for a solitary pancreas transplant. However, the waiting time for CAD kidney transplants is long. Thus the incentive for an LD pancreas transplant is highest in uremic diabetics, whose waiting time for a CAD simultaneous pancreas kidney (SPK) transplant would otherwise be long and most likely require dialysis. The outcomes of an LD kidney procedure first, followed by a CAD pancreas (PAK) procedure, are good,³⁰ but this requires two operations. Outcomes are also good in patients who receive a

simultaneous CAD pancreas and living donor kidney,⁶⁰ but these procedures are logistically difficult for some patients, and waiting time is still involved.

More than 80% of the living donor segmental pancreas transplants in the Registry have been done at the University of Minnesota, and it is the Minnesota experience that is reviewed here. We began to offer LD segmental pancreas transplants in 1979,⁵³ at a time when the rejection rate of CAD pancreata was high.⁵⁴ Initially, we did only solitary pancreas transplants (PAK or PTA) from LDs, with the main aim being an improvement in results. Through the 1980s our solitary pancreas transplant results were superior with living donors.⁷⁶

In the 1990s, the results of solitary pancreas transplants from CAD donors improved dramatically,⁵² making a CAD pancreas after an LD kidney an attractive option from an outcome standpoint.^{30,55} Nevertheless, some uremic diabetic patients who had an LD wanted to avoid two operations and having to wait for either organ. Thus in 1994 we began to do LD segmental pancreas transplants simultaneously with a kidney transplant for these reasons.⁵⁶ An update of our previous reports⁵⁹ on the LD SPK experience is summarized below.

The donors have ranged in age from 24–58 years. Pretransplant, LDs had to have normal oral and intravenous glucose tolerance tests, a threefold increase in first-phase insulin release during intravenous stimulation, and a body mass index below 29 kg/m². The LD SPK recipients ranged in age from 14–58 years, with diabetes duration of 11–29 years. Twenty-four of the LD SPK recipients were not on dialysis pretransplant. Duct management was with bladder drainage (BD) in 32 and duct injection (DI) in 3.

Actuarial patient, kidney, and pancreas (insulin independence) survival rates at 1 year were 100%, 100%, and 86%, respectively, for the LD SPK transplants (Fig. 55-10).

Of the 35 LD SPK transplants, 4 failed for technical reasons, 3 (BD) from thrombosis, and 1 from primary nonfunction (duct injected). There were two late pancreas graft losses from rejection, and one late kidney loss from hemolytic uremic syndrome. All of the LD SPK recipients are alive. The pancreas graft survival rates are at least as high for LD or for CAD SPK recipients, and the kidney graft survival rates are higher with LDs. Furthermore, two-thirds of the LD recipients avoided pretransplant dialysis, which is usually not possible with CAD transplants.

All 35 of the SPK living donors are alive and insulin-independent. Surgical complications included the need for splenectomy in seven, percutaneous fluid drainage in three, and gastritis in one. Two donors had impaired glucose tolerance; one had a prior history of gestational diabetes, and the other had a BMI above our usual limits. Currently, we exclude individuals from being a segmental pancreas donor who have a history of gestational diabetes. Our current criteria also require segmental pancreas living donors to be less than 60 years old, to have a BMI <29 kg/m², to have all glucose values <150 during an oral GTT, and to have an acute insulin response to intravenous glucose and arginine stimulation of >300% above baseline.

Metabolic perturbations can occur in the donors,⁷⁷ but all donors meeting the criteria itemized above have remained normoglycemic and insulin-independent.

Currently, the main application of LD pancreas transplant is in uremic diabetic patients who desire to avoid the long wait for a

FIGURE 55-10. Patient and graft survival for 35 living related donor simultaneous pancreas and kidney (SPK) transplants at the University of Minnesota (1994–2001).

CAD SPK, and for those who would otherwise have bypassed an LD kidney for a CAD SPK to avoid two operations.

LD pancreas transplantation also has a role as a solitary procedure, particularly in highly sensitized patients with a negative crossmatch against a potential donor. Not all CAD pancreata are currently used for clinical pancreas transplantation, so LDs are not yet needed to alleviate a shortage of organs. This likely will change because the results of CAD solitary pancreas transplantation are now so good.⁷⁸ Once a CAD pancreas shortage exists, there will be an incentive to use LDs for solitary as well as SPK transplants.

SURGICAL TECHNIQUE

For solitary organ pancreas transplants, the main choices facing the surgeon are (1) whether to transplant the whole organ or a segment, (2) how to manage the exocrine secretions, and (3) how to establish venous drainage (portal or systemic).

CAD donor grafts are nearly always transplanted as a whole pancreas, since preservation of the blood supply to the entire gland is possible even when the liver is procured.⁷⁹ A Y-graft of donor iliac artery can easily be used to join the splenic and superior mesenteric arteries of the graft, allowing for a single arterial anastomosis in the recipient. Thus almost all segmental grafts done today are from living donors. Adequacy of segment transplants has been established by metabolic studies.^{9,80} Segmental grafts from CAD donors still have a role when there is a rare anatomic abnormality that does not allow the head of the pancreas to be used, or when there is a compelling reason to split the pancreas into two segments for transplantation to two different recipients, such as when both have a high panel reactive antibody but a negative crossmatch for the same donor.⁸¹ Indeed, as the number of candidates listed for pancreas transplants and waiting times increase, the incentive to split cadaver organs will also increase.

In regard to current management of the exocrine secretions, some groups always use ED,^{43,46} some always use BD,⁷⁴ and for others the approach is dictated by the recipient category.⁵² Both techniques now have a relatively low surgical risk.⁸²

BD allows direct measurement of enzyme activity in the pancreatic graft exocrine secretions. A decrease in urine amylase is a sensitive marker of rejection, even though it is not entirely specific.⁸³ Urine amylase always decreases before hyperglycemia ensues. A rise in serum amylase may precede a decrease in urine

amylase, but serum amylase by itself is less sensitive (it does not always rise, while urine amylase always decreases), and is no more specific for diagnosis of rejection. Thus for solitary pancreas transplants, the rejection loss rate is lower with BD than with other duct management techniques.²⁹ Rejection episodes are detected early with BD, increasing the probability that the process will be reversed by a temporary increase in immunosuppression. If necessary, a rejection diagnosis can be confirmed by a percutaneous biopsy whether the graft is ED or BD.^{84,85}

In the SPK category, isolated rejection of the pancreas is now rare with the immunosuppressants FK506 (tacrolimus) and mycophenolate mofetil (MMF). Rejection episodes affecting both organs are nearly always first manifested by a rise in serum creatinine (easily confirmed by renal graft biopsy). Thus, most transplant centers now use ED for SPK transplants, as has been advocated for years by the Stockholm group.⁸⁶ Although the acute surgical complication rate leading to graft loss may be slightly higher with ED (mainly leaks, the graft thrombosis incidence being about the same with all techniques), the chronic complication rate is lower.⁸⁷ Between 10% and 20% of recipients of BD grafts are ultimately converted to ED because of chronic complications such as metabolic acidosis from bicarbonate loss secreted directly from the pancreas, urinary tract infections related to the enterovesical anastomosis, dysuria, hematuria, or late leaks.¹

ED could be the standard duct management technique for all pancreas transplant categories once immunomodulation strategies that completely prevent rejection episodes are devised.^{88,89} Currently, a rejection episode-free regimen does not exist, so BD gives an advantage in solitary pancreas transplants. For SPK transplants, ED is justifiably the dominant method of drainage.

Another question is whether to drain the venous effluent of the pancreas graft into the recipient's portal or systemic circulation. Portal drainage is more physiologic than systemic drainage,^{90,91} but it is not easily combined with bladder drainage.³⁹ Thus, most portally drained transplants have been done with ED in SPK recipients, and several groups now make it their standard technique.^{44–46,92}

With both systemic and portal drainage, the recipients are euglycemic with a normal glycohemoglobin, but portally drained recipients will have lower systemic insulin levels.⁸⁰ However, even with systemic drainage of pancreas grafts, the situation of *de novo* hyperinsulinemia (syndrome X) is not replicated. There is no evidence that there is any detrimental effect of systemic drainage on lipid levels⁹³ or vascular disease.²⁴ Most groups have continued to use systemic venous drainage for ED SPK transplants. On the other hand, there is no reason not to mimic nature, and most likely there will be a shift toward portal drainage for ED SPK transplants, particularly if the reports of fewer rejections with portal drainage are confirmed.^{43,46}

PREVENTION OF GRAFT REJECTION

Currently, generalized immunosuppression must be given for all organ or cellular transplants.¹⁵ From the mid-1980s through the mid-1990s, cyclosporine in conjunction with either azathioprine or steroids were the mainstays of maintenance immunosuppression.⁶⁸ Many protocols included induction immunosuppression with heterologous antibody anti-T-cell agents.¹ Since the mid-1990s, FK 506 (tacrolimus) and mycophenolate mofetil (MMF) have been used widely in pancreas transplants, and both immunosuppressants have been associated with improvement in pancreas graft survival

rates.^{66,70,78} In addition, steroids have been successfully withdrawn from pancreas transplant recipients without precipitating rejection,⁷² or have been avoided altogether.⁹⁴

In the groups at highest risk for rejection, PTA and pretransplant immunosuppression have been associated with a decrease in both rejection episodes and immunologic graft loss.⁹⁵ Finally, advances in antimicrobial prophylaxis have also been an important advance in allowing the immunosuppressive drugs to be used so effectively.^{96,97}

EFFECTS OF PANCREAS TRANSPLANTATION ON METABOLISM AND SECONDARY COMPLICATIONS OF DIABETES

A successful pancreas transplant nearly always establishes euglycemia and insulin independence in the recipient, with constantly normal glycosylated hemoglobin levels.⁸ Minor metabolic perturbations can exist in some pancreas recipients, and are of academic interest,⁹⁸ but do not affect day-to-day life. Pancreas graft function has been extremely durable⁹ as illustrated by studies in patients followed for more than 10 years (Figs. 55-11 and 55-12). In diabetic patients with impaired hypoglycemic counterregulation, a successful pancreas transplant can permanently restore counterregulatory mechanisms. Pancreas transplantation is the best treatment for diabetic patients afflicted with hypoglycemic unawareness.⁹⁹

As mentioned in the section on surgical techniques, most pancreas transplants are drained via the systemic venous system and thus induce a degree of hyperinsulinemia. Portal drainage of the graft venous effluent avoids this potential problem.⁴² On the other hand, a beneficial effect of pancreas transplants on lipid metabolism occurs even with systemic drainage.⁹³

In regard to the effect on secondary complications, it is clear that a successful pancreas transplant performed early in the course of diabetes would prevent their occurrence. There is also an effect on established lesions, as summarized in previous reviews.^{24,100} The rapidity with which neuropathy improves is quite variable, sometimes occurring early and sometimes evolving over several years¹⁴⁻²¹. Severely neuropathic patients have a very high mortality rate. Remarkably, after a pancreas transplant, the mortality rate is much reduced, independent of the effect on neuropathy.^{101,102} The beneficial effect of pancreas transplantation on survival of diabetic

FIGURE 55-11. Fasting blood glucose levels in 16 type 1 diabetic recipients at increasing numbers of years after pancreas transplantation. Lines connect sequential data that were available in 14 of the 16 patients. Inset shows mean $\pm$ SE of the data for the group.

FIGURE 55-12. Levels of fasting blood glucose, HbA_{1c}, and intravenous glucose tolerance in type 1 diabetic recipients 10–18 years after whole or segmental pancreas transplantation, compared with age-, sex-, and BMI-matched nondiabetic control subjects. No significant differences were found.

patients, particularly those that are nephropathic, is also well documented.^{52,103-108} Pancreas transplantation can prevent the occurrence of diabetic nephropathy in renal allografts.^{22,23}

In regard to diabetic nephropathy in native kidneys, remarkably, in long-term PTA recipients, established structural changes of diabetes in the kidney can reverse between 5–10 years after transplant¹⁰⁹ (Figs. 55-13 and 55-14). Thus pancreas transplants alone could be used earlier in the course of diabetic nephropathy to prevent the otherwise inevitable deterioration.

In regard to vascular disease, an improvement in microvascular microangiopathy following pancreas transplantation has been described.¹¹⁰ Improvement of left ventricular function¹¹¹ and a decrease in atherosclerotic risk factors¹¹² following pancreas-kidney transplantation have also been reported.

Several reviews on the effect of pancreas transplantation on secondary complications have been published, including articles describing a favorable effect on microcirculation.^{24,100,113} These reviews also include studies on quality of life. All show that patient satisfaction is higher in SPK and PAK than in kidney transplant alone (KTA) recipients due to many factors, including dietary management, and that there is a positive impact on the recipient's family as well.^{18,114} Nearly uniformly, PTA recipients state that management of immunosuppression is easier than management of diabetes.

RECIPIENT SELECTION

Not every diabetic patient can undergo pancreas transplant because of the shortage of suitable CAD donors. It is unlikely that living donors can make up this deficit, because even for kidney transplants, where living donation is widely promoted, the shortage is large. In the United States, there are approximately 30,000 new cases of T1DM each year, and there are only approximately 5000 CAD donors annually. Thus even if every CAD donor was used for a pancreas transplant with the organ split into two parts, the pancreas transplant rate would be only one-third of the new T1DM case rate.

Pancreas transplantation can also establish a euglycemic state in patients with T2DM,¹⁷ making the gap between available donors and potential candidates even greater. Thus a strategy of allocating the available organs to those who would benefit the most (e.g., to alleviate hypoglycemic unawareness) is needed. Pancreas transplantation can be used to prevent secondary complications of diabetes, and those at high risk (if they can be identified) should have priority.

FIGURE 55-13. Thickness of the glomerular basement membrane, at baseline and 5 and 10 years after pancreas transplantation. The shaded area is the normal range. (Reproduced with permission from Fioretto et al.¹⁰⁹)

Even though it is late in the course of the disease, the most obvious patients to undergo pancreas transplant are those who also need a kidney transplant and are obligated to immunosuppression. For those who do not have a living donor for the kidney, an SPK transplant from a CAD donor makes sense. For those that have an LD, the ideal approach would be an SPK from this source. If the donor is suitable only for a kidney, it would still be preferable to perform an LD kidney transplant first with either a simultaneous or subsequent CAD pancreas.⁶⁰ Long-term graft functional survival rates for LD kidneys have been consistently higher than for CAD donor kidneys, and the insulin-independence rate with PAK transplants are nearly identical to those of SPK transplants.^{29,30}

The PAK option is vastly underutilized. An LD kidney followed later by a CAD pancreas avoids long waiting times to get off dialysis or avoids the need for dialysis altogether, and gives the highest probability of remaining dialysis-free long term. Thus for the uremic diabetic the best option would be an LD SPK transplant.

FIGURE 55-14. Photomicrographs of renal biopsy specimens obtained before (left) and 10 years after (right) pancreas transplantation. Specimens were taken from a 33-year-old woman with type 1 diabetes of 17 years' duration at the time of transplantation. (Reproduced with permission from Fioretto et al.¹⁰⁹)

Pretransplant

10 years posttransplant

the second best option an LD KTA with a CAD pancreas simultaneously, the third best option an LD KTA followed by a PAK, and the fourth a CAD SPK.

In regard to nonuremic diabetic patients, there are no satisfactory treatments for patients with hypoglycemic unawareness. Thus strict control is really the only alternative strategy, resulting in high glycosylated hemoglobin levels and an increased risk for secondary complications. A successful pancreas transplant allows such patients to avoid hypoglycemia and gives them the freedom of insulin independence.^{12,99}

In regard to doing PTA early in the course of diabetes before complication occurs, it is logical to do so. Again, only a small percentage of diabetic patients can take advantage of this approach, so it would be ideal to identify those at high risk for secondary complications. Ideally, randomized studies should be done to compare the long-term complication rate of immunosuppression versus the complication rate of diabetes in comparable populations of patients whose diabetic control is only of average difficulty. However, in patients who have more difficulty with diabetic control and who are not able to maintain nearly normal glycosylated hemoglobin levels, the risk of secondary complications is going to be greater than the risk of immunosuppressive complications. In this situation a PTA is a reasonable choice.⁵²

ORGAN ALLOCATION AND FINANCIAL COVERAGE ISSUES FOR PANCREAS AND ISLET TRANSPLANTS

Pancreas or islet transplantation is an expensive treatment for diabetes mellitus, at least for the procedure itself.¹¹⁵ The organ procurement costs are the same for both. Pancreas transplantation requires surgery and a period of hospitalization, while islet transplantation requires processing of the organ. Once the graft is in place, the cost of maintenance immunosuppression is approximately equivalent to the cost of modern diabetic management on an ongoing basis.¹¹⁶

Financial coverage by insurance companies and health maintenance organizations for pancreas transplantation has been variable, but has been provided for all categories by some insurance companies since the 1980s. In general, insurance coverage has been most frequent for SPK transplants and least frequent for PTA transplants, with PAK transplants being intermediate, but the number of insurance companies covering each of the categories has progressively increased. In 1999, Medicare began to cover SPK and PAK transplants, so now virtually every uremic diabetic is financially eligible for a pancreas transplant. PTA coverage is usually decided on a case-by-case basis by the insurance companies that have such a provision.

Pancreas organ allocation from CAD donors is done under the auspices of the United Network for Organ Sharing (UNOS). As for all organs, the pancreas is first offered to patients on a local organ procurement organization (OPO) waiting list; if it is not needed locally, it is next offered regionally, and then nationally. The UNOS policy for local pancreas allocation is based on candidate waiting time. Nationally, allocation is according to match; for multiple candidates with an equivalent match, waiting time is the tiebreaker. Some OPOs have a variance for allocation according to the best match, again with waiting time as the tiebreaker.

In addition, each OPO has to decide whether priority is given first to recipients waiting for a pancreas and kidney transplant, or to

those waiting for a solitary pancreas transplant. Since there is an allocation system for kidney transplants that is also based on waiting time and match, some OPOs allocate a pancreas for SPK transplant only if the patient reaches the appropriate level on the kidney transplant waiting list. If the pancreas is not allocated to a diabetic kidney transplant candidate, it is then allocated to the candidate for solitary pancreas transplant.

In regard to allocation for pancreas and islet transplantation, ideally, patients waiting for either should be on a common waiting list. Conceptually, the allocation system should simply be designed for β -cell transplantation, and the technique (islet or immediately vascularized graft) should be tailored to the individual circumstances of the candidate. A pancreas transplant almost always induces insulin independence in the diabetic recipient. Currently, the β -cell mass that engrafts from islet transplantation may not be sufficient to induce islet independence without an additional transplant.³ On the other hand, single islet transplants have been able to induce insulin independence when done from large donors to small recipients with low insulin requirements.⁴

A utilitarian approach would be to use islets for β -cell replacement therapy in diabetic patients with a low body mass index (BMI) or with low insulin requirements, and to use an immediately vascularized pancreas transplant for those with high insulin requirements. Donors with a high BMI (e.g., 28 kg/m²) could be used for islet transplantation and the smaller donors for pancreas transplantation. By such an allocation scheme, the largest number of candidates could be made insulin-independent with surgery only as appropriate; high-BMI donors for islets to low-BMI recipients, and low-BMI donors for pancreas transplants to high-BMI candidates or those with high insulin requirements.

Just as there is an insufficient number of CAD organs available to treat all who would benefit from kidney, heart, or liver transplantation, the same is true for pancreas or islet transplantation. The number of new cases of diabetes mellitus exceeds the number of CAD organ donors available. Thus for large-scale treatment of diabetes through β -cell replacement therapy, sources other than CAD (or even living) donors will be needed. Medical priority for those least well served by exogenous insulin replacement may be necessary in the future for fair allocation of the few organs available.

FUTURE OF PANCREAS OR ISLET TRANSPLANTATION

Pancreas transplantation is now performed as a routine treatment for uremic diabetic recipients of kidney transplants, either simultaneously or after the kidney. Such patients are obligated to immunosuppression, and with a successful pancreas transplant can achieve insulin independence as well as a dialysis-free state.

Pancreas transplants alone are less commonly applied because of the need for immunosuppression, but the trade-off to achieve an insulin-independent state is worthwhile for individual patients, particularly those with labile diabetes or hypoglycemic unawareness. A positive effect on secondary complications will occur with early transplantation, and even when done late can have an impact, as has been shown for both neuropathy and nephropathy.²⁴

Almost certainly, the side effects of immunosuppression will decrease as new immunomodulation strategies are developed.⁸⁸ Unless the need for pancreas transplant diminishes (either through preventive or regenerative strategies), the impetus to alleviate the donor shortage for all organ transplants will continue. Xenotrans-

plantation is the long-range answer, and there are attempts being made to genetically engineer pigs as a source of organs that will not incite the vigorous rejection response that normally occurs.¹¹⁷

Not all of the tools necessary to prevent rejection of solid organ xenografts are available. It is likely to be several years before xenotransplantation becomes routine. The generalized immunosuppression necessary to prevent rejection of allografts is relatively mild, preserving host immune defense mechanisms sufficiently to ward off infections. Opportunistic infections are basically xenografts, but are a problem only in allograft recipients who are overimmunosuppressed.¹¹⁸ For xenograft recipients, the level of immunosuppression needed may predispose to opportunistic infections.

Islet xenografts are touted as having an advantage by using immunomodulation or encapsulation.¹¹⁹ Although islet encapsulation has succeeded in animal models as isografts or allografts, once it has been done in a xenograft situation, immunosuppression has been necessary. Even as an allograft, immunosuppression has been necessary when done in autoimmune models. Thus, pancreas or islet xenotransplantation is not a likely option in the near future.

Islet allotransplantation remains a goal in an attempt to minimize surgery. With adequate numbers, islet autotransplantation is nearly uniformly successful in preventing diabetes after total pancreatectomy.¹²⁰ Islet allotransplantation appears to require a larger number of islets,³ but can succeed with a single donor under special circumstances.⁴

All available CAD organs should be used for pancreas (or islet) transplantation, and distributed between uremic and nonuremic patients. The number of uremic diabetic patients should diminish as intensive insulin treatment is universally applied and as pancreas (or islet) transplants alone are done to prevent diabetic nephropathy in the first place. Until preventive or regenerative strategies eliminate the need, transplantation will be a major part of the modern diabetologist's armamentarium.

Islet Cell Transplantation

Gina R. Rayat

Ray V. Rajotte

Gregory S. Korbutt

INTRODUCTION

Current methods for treating insulin-dependent (type 1) diabetes mellitus (T1DM) do not prevent transient episodes of hyperglycemia. Recurrent hyperglycemia has been suggested to cause chronic lesions that can culminate in renal failure, blindness, heart disease, neuropathy, or atherosclerosis. The most definitive study in the field, the Diabetes Control and Complications Trial,¹ clearly showed that with intensive insulin therapy, a 2% decrease in HbA_{1c} significantly reduced the risk of microvascular complications. However, this improvement in HbA_{1c} did not result in normalization of the value (median 7%) and was associated with an increased risk of severe hypoglycemia. In addition, the extraordinary effort required in self-monitoring and providing ongoing management for these patients may exceed the capabilities of many individuals and their health care providers. Thus, a predominant focus of human diabetes research has been the development of better methods to achieve optimal glucose control, so that the disabling complications can be reduced or prevented.

Vascularized pancreas transplantation has become accepted as an alternative therapy for individuals receiving simultaneous kidney transplants. Although occasionally used as a solitary pancreas transplant, the significant risks associated with whole organ transplants usually limit its use to cotransplantation with other organs. Furthermore, pancreas transplantation remains associated with significant morbidity in terms of surgical risk, but is also associated with about 86% graft survival.² Compared to vascularized pancreatic grafts, transplantation of isolated islets offers a number of advantages. For example, islet transplantation is a much simpler and less invasive procedure, which if performed earlier on can potentially result in excellent glucose control and prevent long-term complications. Islet transplantation also has the potential benefit that the donor tissue can be tested and/or pretreated before implantation, thus allowing the possibility of using grafts with defined metabolic or immunological characteristics. This chapter reviews the history and current status of islet cell transplantation.

EXPERIMENTAL ISLET TRANSPLANTATION

Pancreatic islets were first described by Paul Langerhans in 1869, when his thesis as a medical student in Virchow's laboratory was published.³ The possibility of transplanting pancreatic tissue has

interested clinicians and scientists since 1889 when Von Mering and Minkowski⁴ demonstrated that removal of the canine pancreas resulted in hyperglycemia. However, the concept of separating islet endocrine cells from the exocrine tissue of the pancreas was not examined until 1964, when Hellerstrom used microdissection to isolate islets from the rat pancreas.⁵ Since this method was traumatic and islet yield was poor, Moskalewski⁶ used the enzyme collagenase to digest guinea pig pancreas in an attempt to improve islet recovery and function. Lacy and Kostianovsky⁷ further improved this technique by intraductal distention of the rat pancreas with collagenase to disrupt the exocrine tissue prior to mechanical mincing and enzymatic digestion of the gland. Methods to purify islets from contaminating exocrine tissue began by using centrifugation in sucrose gradients.⁸ Later centrifugation on Ficoll gradients proved to be the most effective means to purify islets from contaminating exocrine tissue because it provided a better osmotic environment for the islets.⁹ Although numerous methods and gradients for islet purification have been proposed, Ficoll still remains the gradient of choice for both animal and human pancreases.

The first report of transplanting isolated rodent islets was in 1970 by Younoszai and associates.¹⁰ They demonstrated temporary amelioration of chemically induced diabetes in rats. Subsequently, Ballinger and Lacy¹¹ achieved euglycemia following transplantation of 400–600 islets in the peritoneal cavity or thigh muscle of inbred diabetic Lewis rats. In 1973, Reckard and Barker¹² reported complete normalization of glucose levels in rats for 7 months following intraperitoneal injection of 800–1200 autologous islets. Kemp and colleagues¹³ demonstrated that approximately 800 islets could completely normalize plasma insulin and glucose concentrations when embolized to the liver by the portal vein. The physiologic significance of the hepatic portal circulation has been demonstrated by a number of investigators.^{14–18} Islets have also been transplanted into the peritoneum,^{11–13,19–21} liver,^{14,15,21,22} spleen,^{23,24} a surgically created peritoneal-omental pouch,²⁵ the renal subcapsular area,^{16–18,26,28,29} the testicles,³⁰ the ventricles of the brain,³¹ and the thymus.³² With respect to transplantation site, the most consistent results occurred when the graft was placed in a highly vascular bed with portal venous drainage.

The experimental success of islet transplantation in rodents prompted studies in larger animals, including primates, with the overall goal to use this therapy for the treatment of patients with type 1 diabetes. It soon became apparent that the standardized isolation techniques for rodent islets could not be applied to the more compact

and fibrous mammalian pancreas, in particular the human pancreas.^{33–38} Unlike inbred rodent models, where it is feasible to use multiple donors per recipient, multiple donors could not be used in a population of outbred large animals, such as dogs, since allogeneic islets would be rejected before long-term function of a technically successful graft could be determined. Merkovitch and Campiche,³⁴ therefore, eliminated the islet purification step and reversed diabetes in 20 of 25 dogs with intrasplenic autografts of dispersed pancreatic fragments isolated from the tail portion of the pancreas. Kretschmer and coworkers³⁵ improved these results by achieving normoglycemia in 20 of 21 dogs by intrasplenic transplantation of pancreatic fragment autografts prepared from the entire gland. Preparation of the grafts involved mincing the entire pancreas in a mechanical tissue chopper followed by collagenase digestion in a shaking water bath. Using these techniques, or modifications thereof, autografts of dispersed pancreatic fragments prepared by enzymatic digestion and mechanical dispersion were shown by other investigators to reverse the diabetic state in dogs.^{39–41}

More efficient means of digesting the large mammalian pancreas were subsequently developed when collagenase was introduced into the duct by direct injection.^{42–46} This effective delivery of collagenase to the connective tissue stroma of the islet–acinar interface resulted in a greater separation of the islets from the surrounding exocrine tissue. Using these methods for pancreas digestion, successful intraportal autotransplantation of purified canine islets became a reality. These technical advancements, along with many modifications, also led to their use for the isolation of islets from the human pancreas. Gray and colleagues⁴⁷ reported that prewarming the collagenase to 39°C improved digestion of acinar tissue and the use of a mesh filter also improved the islet yield. Ricordi and coworkers⁴⁸ modified this method in pigs, by injecting collagenase prewarmed to 24°C, dispersing pancreatic cells with a mechanical macerator, and purifying with mesh filtration and Ficoll density gradient centrifugation. In 1988, Ricordi and colleagues⁴⁹ modified this procedure and developed an automated method for isolation of human pancreatic islets. Unfortunately, the lack of consistent and effective lots of enzymes used in the isolation of canine and human islets had prevented the successful recovery of large numbers of viable islets, thus hindering research in this area for many years. A major advance in islet isolation took place recently with the development of Liberase-HI and Liberase-CI (Boehringer-Mannheim). These purified enzyme blends helped eliminate the lot-to-lot variability often associated with crude collagenase and improved the effectiveness of human and canine islet isolation.^{50,51} In 1999, based on a technique first described by Horaguchi and Merrell⁴² and later modified by Warnock and associates,⁴⁵ Lakey and coworkers confirmed that retrograde intraductal delivery of Liberase-HI using a recirculating controlled perfusion system provided superior human islet recovery and survival when compared to syringe loading.⁵² By providing controlled perfusion pressures and temperature during loading of the enzyme into the pancreas, the recirculating controlled perfusion system more effectively delivers the collagenase to the islet–acinar interface, resulting in a greater separation of islets from the surrounding exocrine tissue.^{45,52}

In an attempt to identify donor factors that can influence islet recovery and function, Lakey and coworkers conducted a retrospective study of 153 human islet isolations over a 3-year period.⁵³ This multiple regression analysis of postdigestion and postpurification islet recovery identified donor age, body mass index, and local procurement team to be positively correlated with isolation success. Elevated blood glucose levels, frequency and increased dura-

tion of cardiac arrest, and prolonged cold storage of the pancreas prior to islet isolation were identified as factors that were negatively correlated with isolation success.⁵³ Therefore, rigorous selection criteria of suitable pancreases for processing and potentially individualized isolation protocols based on the several donor variables identified improved consistency in human islet isolation.²² The ability to consistently isolate a higher quality and quantity of islets from human pancreases has been a key to the development and continuation of experimental and clinical trials in islet transplantation as a realistic treatment option for patients with type 1 diabetes.

CLINICAL ISLET TRANSPLANTATION

According to the International Islet Transplantation Registry,⁵⁴ from 1974 to 1989, a total of 90 human islet allografts were conducted. Between 1990 and December 31, 2000, 394 were performed. Recipients of these initial human islet allografts were predominantly type 1 diabetic patients with a kidney graft (either simultaneous or prior to an islet graft), nonuremic type 1 diabetic patients, or pancreatectomized patients receiving a liver graft due to upper abdominal exenteration. Until 1989, virtually all attempts to correct basal hyperglycemia in humans failed.⁵⁴ Moreover, of the 267 human islet allografts from 1990 to 1998, only 12.4% resulted in insulin independence for periods of more than 1 week, and only 8.2% have done so for periods greater than 1 year.⁵⁴ The poor outcome with the initial attempts at human islet transplantation can be attributed to implantation of an insufficient β -cell mass and the use of non-optimal immunosuppression. More recently, techniques for isolating large numbers of human islets have improved, permitting renewed attempts at clinical islet transplantation.^{55–59} Furthermore, with the increased availability of novel and more specialized immunosuppressive agents, strategies are now available specifically for islet grafts that will provide protection for both allograft rejection and autoimmune destruction as well as avoiding diabetogenic side effects.⁶⁰

In 1999, the Edmonton Group developed a glucocorticoid-free immunosuppressive protocol for use in a clinical islet transplant trial that included patients with brittle type 1 diabetes.⁶⁰ This initial trial was conducted in seven patients receiving islet grafts alone as well as exhibiting either severe hypoglycemic unawareness or uncontrolled diabetes despite compliance with an insulin regime. Immunosuppression was initiated immediately before transplantation using sirolimus (Rapamune), low-dose tacrolimus (Prograf), and a monoclonal antibody against the interleukin-2 receptor, daclizumab (Zenapax). No glucocorticoids were given at any time during the trial. As soon as sufficient numbers of islets were available for transplantation, patients were given prophylactic intravenous antibiotics (vancomycin and imipenem) and oral supplementation with vitamin E, vitamin B₆, and vitamin A. Inhaled pentamidine (for PCP prophylaxis) was given once a month after transplantation, and oral ganciclovir was given for 14 weeks to reduce the risk of graft loss and protect against lymphoproliferative disorder. Patients received an average of 800,000 islet equivalents, which were isolated using xenoprotein-free medium and transplanted immediately after isolation via transhepatic injection into the portal vein. Islet donors were matched for blood type and lymphocytotoxic antibodies but not HLA. Insulin therapy was discontinued after each transplantation and not resumed unless serum glucose concentrations rose above 200 mg/dL, in which case another transplant was

performed. Blood glucose levels were checked seven times per day. Patients also underwent oral glucose tolerance testing. HbA_{1c} and C-peptide levels were also measured.

All seven patients quickly attained sustained insulin independence after receiving islets from two donor pancreases. One recipient required a third transplant from an additional two donors. The mean HbA_{1c} values were normal in all transplant recipients. The amplitude of blood glucose fluctuations was dramatically decreased, and further episodes of severe hypoglycemia, common before transplantation, did not occur. Detectable C-peptide levels were measurable at 3 and 6 months. Glucose tolerance was not completely normalized; whereas none of the recipients had diabetic oral glucose tolerance tests, five had impaired glucose tolerance, and two had impaired fasting glucose.

In a more recent publication of the results from the Edmonton Group, data were provided on 12 type 1 diabetic patients receiving islet allografts with the same protocol and with a median follow-up of 10.2 months, with the longest at 20 months.⁶¹ Each patient received approximately 850,000 islet equivalents isolated from two to four donor pancreases. In 11 of 12 patients, insulin independence was obtained when a minimum of 9000 islet equivalents/kg were implanted intraportally. The one patient that required daily insulin despite receiving 9000 islet equivalents/kg experienced a thrombosis in a peripheral portal vein, which may have contributed to a partial loss of islet function. All patients, however, discontinued insulin after the final transplant. The pretransplant fasting and meal tolerance–stimulated glucose levels were 12.5 ± 1.9 and 20.0 ± 2.7 mmol/L, respectively, and were shown to significantly decrease, with posttransplant level of 6.3 ± 0.6 and 7.5 ± 0.6 mmol/L, respectively. All patients were shown to have sustained insulin productions, as indicated by elevated C-peptide levels after a meal tolerance test. Four patients were reported to have normal glucose tolerance, five exhibited impaired glucose tolerance, and three required oral hypoglycemic agents and low-dose insulin (<10 U/day). The most adverse complication observed in these patients was an increase in serum creatinine in two individuals who already had elevated serum creatinine. Other complications included increased blood pressure (four patients) that required antihypertensive therapy and elevated cholesterol where lipid-lowering therapy was required in three of these five patients. Nonetheless, none of the serious surgical complications that are associated with whole-pancreas transplant were evident in any of these 12 patients, and the procedure was simple and well tolerated. Even though these patients have encountered a few complications with these trials, the longer the patients remain off insulin, the more they have significantly improved glucose control, have no episodes of hypoglycemia, and have an enhanced quality of life. Furthermore, this series of clinical transplants is the first to provide a scientific means of assessing the long-term efficacy of functional human islet allografts. In particular, it is now possible to define and, more importantly, optimize graft characteristics with respect to cellular composition and functional viability, which may be critical for long-term graft survival.

SUPPLY OF ISLET TISSUE

A limited supply of human donor pancreas makes it unrealistic for all persons with diabetes to achieve insulin independence through islets from multiple donors. Since it has been estimated that there are approximately 1–1.5 million islets in a human pancreas^{62–64}

and the recipients of the Edmonton Protocol have required approximately 800,000 islet equivalents to achieve insulin independence, it is conceivable that a single donor pancreas can be used to treat one recipient. However, in the most optimal isolations, islet recovery is often 40% or lower, thereby necessitating the need for multiple pancreases for each recipient or developing an unlimited supply of insulin-producing tissue.

One significant obstacle for successful, widespread clinical islet transplantation is the limited availability of insulin-producing tissue. Each year in the United States, approximately 5000 organ donors are available, and only a portion of these are suitable for islet transplantation.⁶⁵ Yet there are approximately 30,000 new cases of type 1 diabetes each year.⁶⁶ Clearly, the demand for insulin-producing tissue is higher than the availability of human islets. In an attempt to overcome the “islet supply” problem, insulin-producing tissue from abundant and readily accessible sources is being considered for clinical transplantation. These sources include (1) porcine and bovine islets,^{67–71} (2) fish Brockmann bodies,^{72,73} (3) genetically engineered insulin-secreting cell lines,^{74,75} and (4) *in vitro* production of human pancreatic islet tissues.^{76,77} Most studies have shown there is limited *in vitro* growth of adult islet cells of any species, but several recent reports have found cell proliferation using cultures of islet preparations with extracellular matrix and growth factors. Two recent studies demonstrated that human pancreatic ductal tissue can be expanded in culture and then induced to differentiate into islet tissue *in vitro*.^{76,77} Our group has also demonstrated that human pancreatic ductal cells can be successfully differentiated *in vitro* into insulin-positive cells (Fig. 56-1). However, due to the limited availability of the ductal tissue as well as its limited ability to differentiate into pancreatic endocrine cells, further optimization of conditions are needed to generate yields of islet tissue that can make an impact on islet isolation.

Considering that less than 95% of the pancreas is exocrine, it would be extraordinary if this normally discarded majority fraction could be converted to endocrine tissue suitable for transplantation. Indeed, the hypothesis exists that acinar cells have the innate ability to “transdifferentiate” into endocrine islets.^{78,79} Remarkably,

FIGURE 56-1. Immunohistochemical localization of insulin-positive cells following tissue culture of human pancreatic ductal tissue. Human pancreatic ductal cells were cultured as monolayers in four-well chamber slides for 16 days. Insulin-positive cells were absent at the beginning of culture and were found scattered throughout the monolayer after 16 days' culture.

digested human pancreatic acinar cells (amylase-positive, cytokeratin-19 negative) take on a ductal phenotype (amylase-negative, cytokeratin-19 positive) after only a few days culture.⁸⁰ Notably, the possibilities of overgrowth of the acinar population by a ductal subpopulation or selective adherence were excluded in this study. This process is associated with the induction of PDX-1 expression,^{81,82} a homeodomain transcription factor believed to be a master regulator of β -cell development. The decisive role of PDX-1 in endocrine differentiation was recently demonstrated in the liver, whereby targeted expression of PDX-1 resulted in insulin gene expression.⁸³ However, while the exocrine-derived ductal-like cells express PDX-1, little insulin gene expression occurs.^{81,82} The loss of insulin expression also occurs in expanded β cells, despite retained PDX-1 expression.⁸⁴ Nevertheless, if the differentiation potential of these putative pancreatic stem cells is confirmed, as recently suggested,^{76,77,85} this model may have immediate clinical repercussions.

The establishment of pluripotent embryonic stem cells^{86,87} and embryonic germ cells⁸⁸ introduces a new potential source for cell therapy for the treatment of patients with type 1 diabetes. Glucose-sensitive insulin secreting cells have been produced from mouse embryonic stem cells.^{89,90} In one study, which utilizes a gene trap strategy to clone insulin-producing cells, these clones exhibited regulated insulin secretion *in vitro* and achieved euglycemia following transplantation in diabetic mice.⁸⁹ However, 40% (6 of 15) of the recipients of these embryonic stem cells became hyperglycemic at about 12 weeks posttransplant.⁸⁹ In a subsequent study, insulin expressing as well as other pancreatic endocrine cells were produced from mouse embryonic stem cells.⁹⁰ These endocrine cells were shown to self-assemble into three-dimensional cell clusters similar in morphology to normal pancreatic islets. These cell clusters were responsive to glucose *in vitro*; however, they were shown to contain 50 times less insulin per β cell than found in normal β cells, thereby suggesting an immature phenotype. When culturing undifferentiated human embryonic stem cells in either adherent or suspension tissue culture, Assady and co-workers⁹¹ observed spontaneous differentiation of numerous insulin-positive cells. These newly differentiated cells were associated with the expression of β -cell-related genes and shown to secrete insulin into the tissue culture medium, but were not shown to be glucose-responsive.⁹¹ Taken together, these studies demonstrate that the engineering of embryonic stem cells to produce an abundant source of islet tissue for transplantation holds a growing promise for finding a solution to the supply of insulin-producing tissue.

Although the production of islet tissue from pancreatic stem cells is exciting and encouraging, there still are ethical concerns associated with embryonic cells as well as the limited potential of adult pancreatic stem cells to generate sufficient quantities of islet tissue for the treatment of patients with diabetes. Thus, porcine islets are still being considered as an unlimited supply of insulin-producing tissue. Pigs are attractive because they have many physiologic similarities to humans and their glucose levels are similar to those of humans. In addition, pigs can be raised in a controlled environment and subjected to genetic manipulation, thus making the use of their organs and tissues as xenografts more acceptable.

The first description of a method for the isolation of adult porcine islets appeared in 1974 when Sutherland and colleagues³⁶ used a modification of the collagenase technique described for rat isolation to prepare porcine islets for autotransplantation. In 1986, Ricordi and coworkers⁴⁸ reported that an average of 80,000 islets could be prepared from adult pigs by an enzymatic and mechanical

procedure. Marchetti and colleagues⁹² were able to isolate an average of 500,000 islets per adult pig pancreas using a method based on collagenase digestion and filtration of the digested tissue. Warnock and colleagues⁹³ reported that remarkable purity can be obtained from their isolation technique, but the majority of adult pig islets were lost during the purification stage. These losses, which also occur during subsequent tissue culture, are due predominantly to the excessive fragility of the adult porcine islet. In spite of the occasional advance in the isolation of adult pig islets, there still remains serious problems in obtaining intact, viable adult pig islets to provide a source of islet tissue for transplantation.

The use of fetal porcine islets for treating patients with type 1 diabetes was performed by Groth and coworkers⁶⁸ in Sweden. Although there was no evidence to indicate engraftment of the fetal cells, all patients in this study tolerated the procedure well and no adverse effects were recorded. Unlike adult pig islets, tissue culture of collagenase-digested fetal porcine pancreas produces viable islet-like cell clusters⁹⁴ that have the ability to cure diabetes in nude mice within 2 months posttransplantation.⁹⁴ A general finding, however, in rat,⁹⁵⁻⁹⁸ porcine,⁹⁴ and human fetal pancreatic β cells is that they exhibit a poor insulin secretory response to glucose, and the onset of maturation of glucose-induced insulin secretion is more evident in the postnatal period.⁹⁵⁻⁹⁸ Thus, recent attention has focused on the potential of pancreatic cells obtained from neonatal pigs.⁶⁷

Neonatal porcine islets have the advantage of being more mature than the fetal islets and yet maintain considerable capacity for growth. Korbitt and colleagues⁶⁷ developed a simple, standardized procedure for isolating large numbers of neonatal porcine islet cell aggregates with a reproducible and defined cellular composition. After 9 days of culture, the average number of neonatal porcine islet cell aggregates recovered from one pancreas was approximately 50,000. As opposed to adult pig islets, which are known to consist of approximately 80–90% endocrine cells, neonatal porcine islets consist primarily of 35% fully differentiated endocrine cells and 55% epithelial cells or endocrine precursor cells.⁶⁷ *In vitro* viability assessment of the cultured islets showed that in the presence of 20 mmol glucose, the islets were capable of releasing seven-fold more insulin than at 2.8 mmol glucose. When exposed to 20 mmol glucose plus 10 mmol theophylline, the stimulation index increased to 30-fold compared to basal release. Moreover, transplantation of 2000 neonatal porcine islet cell aggregates (consisting of 6×10^5 β cells) under the kidney capsule of alloxan-induced diabetic nude mice corrected hyperglycemia in 100% (20/20) of recipients within 8 weeks posttransplantation.⁶⁷ Examination of the neonatal porcine islet grafts revealed that they were largely composed of insulin-positive cells and the cellular insulin content of these grafts was 20- to 30-fold higher than at the time of transplantation. These results indicate that abundant neonatal porcine islets that have the potential for growth can be routinely isolated in the laboratory and may possibly be used for clinical transplantation. Ultimately, the availability of an unlimited supply of insulin-producing tissue would solve the problem of donor supply for the treatment of patients with type 1 diabetes.

PREVENTION OF ISLET GRAFT REJECTION

It has been suggested that the predominant pathway of islet allograft rejection is through direct antigen presentation by donor-type APC.⁹⁹⁻¹⁰¹ Thus, donor tissue has been pretreated to reduce its

immunogenicity, placed in immunoisolation devices, or transplanted into immunoprivileged sites. The main rationale for pretreating donor islets is to eliminate the need for continuous immunosuppression. Various methods of pretreating islets prior to allografting have been demonstrated to be successful in rodent models. Isolated islets have been pretreated to eliminate or inactivate major histocompatibility complex (MHC) class II-bearing cells, which are known to exert potent immunostimulatory effects.^{102–105} Faustman and colleagues^{100,105} demonstrated that islet grafts remained functional in allogeneic recipients preexposed to a cell-specific antibody cytotoxicity reaction, which selectively destroys Ia-expressing or dendritic cells before transplantation. This procedure was marginally successful, however, when used by researchers in other laboratories.^{106,107} The use of ultraviolet light to inactivate allostimulatory cells for prolonging rat islet allografts was reported by Lau and coworkers.¹⁰⁸ However, when tested in experiments using rats with a stronger allogeneic response, pretreatment by ultraviolet light required temporary immunosuppression to permit survival of donor tissue.¹⁰⁹ Islets have also been cultured to reduce islet immunogenicity, either at 24°C¹¹⁰ or at 37°C in the presence of a gaseous phase containing 95% oxygen.¹¹¹ Lacy and colleagues¹¹⁰ demonstrated that culture at 24°C for 7 days prolonged survival of allogeneic rat islets, provided the recipients received a single injection of antilymphocyte serum. Interestingly, Markmann and coworkers¹¹² showed that the reduced immunogenicity of rat islets cultured at 24°C is correlated to a reduction in endocrine cells' class I MHC antigen expression rather than to the depletion of class II-positive cells. Warnock and associates¹¹³ reported that low-temperature culture of dog islet allografts in combination with low doses of cyclosporine improved survival; however, grafts failed after cessation of cyclosporine treatment. In addition, human islet allografts were also rejected despite the use of immunosuppression and low-temperature culture for 7 days.¹¹⁴ These studies indicate that although pretreatment can prevent islet allograft rejection in mice and rats, its efficacy in larger animal models is highly dependent on immunosuppressive treatment.

Prevention of experimental islet allograft rejection has also been tested by placing islets in immunoisolation devices constructed of semipermeable membranes separating donor tissue from the recipient's immune system. These devices consist of synthetic membranes that allow diffusion of low-molecular-weight substances (i.e., glucose, insulin) yet exclude cellular contacts between donor and host cells as well as passage of larger-molecular-weight molecules (i.e., immunoglobulins). Islets have been immunoisolated by placing them in biohybrid chamber anastomosed to the vascular system,¹¹⁵ diffusion chambers,^{116,117} and microcapsules.^{118,119} Although numerous studies have shown successful reversal of diabetes by transplanting alginate microencapsulated rodent islets in chemically induced diabetic recipients, many of these reports have been difficult to reproduce, and moreover, there has been limited success in the NOD mouse model. More recently, however, Duvivier-Kali, et al. have described a novel microencapsulation technique that provides complete protection of mouse islets against allojection as well as the recurrence of autoimmune diabetes.¹²⁰ This technique utilizes a simple, highly biocompatible barium alginate membrane without a traditional permselective component.

Many sites have also been explored for their potential of providing an immunoprivileged environment for islet grafts. Dispersed pancreatic islet cells were shown to restore normoglycemia

following intracerebral allotransplantation in diabetic rats.³¹ When implanted into the testes, concordant islet xenografts were shown to exhibit prolonged survival.³⁰ Korbitt and colleagues developed a novel cellular therapeutic approach to engraft and protect islet grafts from immune-mediated destruction. The approach uses Sertoli cells to create an immunologically privileged site that protects rodent islet grafts from allogeneic rejection,¹²¹ as well as autoimmune destruction in NOD mice,^{122,123} without requiring chronic immunosuppression. Interestingly, it was shown that Sertoli cell-secreted transforming growth factor- β 1, not FasL, was the underlying mechanism that was responsible for protecting the grafts from autoimmune destruction.¹²³

Since porcine islets are being considered as a potential source of insulin-producing tissue for clinical transplantation, studies to further understand the rejection process as well as prevention of xenograft rejection have been conducted. In solid organ xenotransplantation, it has been demonstrated that a major barrier to discordant (e.g., pig-to-human) xenotransplantation is the occurrence of hyperacute rejection (HAR). HAR is a process believed to be initiated when naturally occurring xenoreactive antibodies in the recipient's sera binds to antigens present on the surface of endothelial (and other) cells within the xenograft. In turn, antibody binding activates complement, which rapidly destroys the transplanted organ or tissue.^{124–129} HAR is characterized pathologically by severe endothelial cell aggregation of platelets to form thrombi, infiltration by neutrophils, edema, and interstitial hemorrhage.^{126,130} All of these effects are the result of endothelial cell activation and lysis by the combined action of recipient antibodies and complement.^{124,128} The most important target for these antibodies has been identified as the carbohydrate gal α (1,3)gal.^{131–136} This epitope is present in high concentrations on all porcine endothelial cells,^{133,136} and has also been detected on fetal porcine islet cells.^{137,138} Rapid destruction of an islet graft has been described in a rabbit-to-primate model,¹³⁸ and it has been demonstrated that neonatal porcine islet β cells express gal α (1,3)gal and are susceptible to cytotoxicity mediated by human antibody and complement.^{139,140} To develop a strategy to protect porcine islets from this form of destruction, Rayat and coworkers¹⁴¹ demonstrated that microencapsulating neonatal porcine allows protection of neonatal porcine islets from the cytotoxic effects of human antibody and complement *in vitro*.

In addition to humoral-mediated rejection, T cells are also capable of inducing xenograft rejection and are likely to be the most significant barrier to successful xenotransplantation.¹⁴² It has been suggested that islet xenograft rejection appears to be less dependent on donor APC than allograft rejection.¹⁰¹ In contrast to allograft rejection where CD8+ T cells play a major role, CD8+ T cells are not required for acute xenograft rejection.¹⁰¹ Rather, CD4+ T cells appear to be the predominant T-cell subset involved in porcine islet graft rejection.^{143–145} Murray and associates¹⁴³ demonstrated that neonatal porcine islets do not express sufficiently high levels of costimulatory and/or adhesion molecules to either activate human CD8+ T cells or to be effective targets for activated human cytotoxic lymphocytes. Moreover, this study also suggests that neonatal porcine islets may not be destroyed by a natural killer cell or cytotoxic lymphocyte-mediated lytic mechanisms after transplantation into humans.¹⁴³ These studies on the experimental prevention of islet allogeneic and xenogeneic rejection provide novel approaches for permitting long-term graft survival, which stimulate attempts in larger animal models for their ultimate application in patients with type 1 diabetes.

CONCLUSION

In the 1970s, normoglycemia was achieved in rodents with chemically induced diabetes following islet transplantation. Twenty years later, islet transplantation became a clinical reality, resulting in long-term insulin independence in only a few isolated cases. As of January, 2001, 12 patients with type 1 diabetes had received islet transplants using the Edmonton protocol.^{60,61} All recipients achieved insulin independence and exhibited significant improvements in their glycemic control and were no longer at risk for severe hypoglycemia. Several lessons have been learned from this experience with the Edmonton protocol. First, prolonged insulin independence is now achievable with a sufficient mass of viable islets and using an appropriate immunosuppressive protocol. Second, functional islet survival appears to be determined by the characteristics of the islet preparation, such that cold-ischemia time of the donor pancreas is an important determinant of islet viability and should be minimized.⁶¹ Finally, these short-term results are extremely encouraging and provide the impetus for continued research in this area.

New Treatments for Diabetes Mellitus: Outlook for the Future

Lester B. Salans

INTRODUCTION

The importance of achieving and maintaining normal or near-normal blood glucose levels ("tight" glucose control) in individuals with diabetes mellitus is well established. In the great majority of diabetic patients, however, glycemic levels necessary to completely control the disease and to eliminate chronic complications are not achieved. As a result, the disease progressively worsens over time and complications develop. Research advances have provided new management tools to achieve tight glucose control and treatment of diabetes has improved, but the intensive therapeutic regimens required are neither practical nor feasible for many patients. Even under circumstances in which best current treatment is optimally applied by highly motivated patients, tight control of blood glucose greatly reduces, but does not entirely eliminate, disease progression and complications. While this is a significant advance over past treatments, it is insufficient and limited to too few individuals. Clearly, there is a need for still better treatments and better treatment methods.

This chapter will review some of the major shortcomings of current treatment and treatment approaches for type 1 (T1DM) and type 2 diabetes mellitus (T2DM), and within this context will highlight some of the pharmacologic agents and technologies under investigation and development for the treatment of diabetes in the future. New therapies for prevention and treatment of diabetic complications are also discussed. The focus of the chapter is on blood glucose control, although the importance of controlling other risk factors such as dyslipidemia and hypertension is fully recognized (see Chaps. 47 and 48).

T1DM: TREATMENT SHORTCOMINGS

Insulin is Not Delivered Physiologically

Current methods of insulin replacement do not mimic physiologic glycemic control closely enough. Delivery of insulin by subcutaneous injection and insulin pumps does not adequately imitate the control of blood glucose achieved by normal pancreatic β (beta) cells, which continuously adjust insulin secretion according to the prevailing blood glucose. Subcutaneous administration by injection and pump delivers insulin to the peripheral circulation rather than portally, the physiologic route, thereby bypassing the liver's

ability to modulate peripheral insulinemia. As a consequence of bypassing first-pass hepatic extraction, insulin is delivered to the peripheral tissues in pharmacologic doses, causing chronic exposure to excessive levels of insulin, especially in the fasting or basal state. Chronic hyperinsulinemia impairs insulin action and may increase the risk of diabetic complications.

While providing too much insulin during basal or fasting conditions, current practice often does not provide insulin in sufficient amounts or with the appropriate timing and pharmacokinetics to control mealtime and postprandial glucose levels. As a result, mealtime blood glucose excursions are excessive. Administration of insulin after, rather than before, blood glucose is elevated is not only unphysiologic, but it is also inefficient; much less insulin is required to prevent hyperglycemia than to reduce hyperglycemia.¹

Intensive Treatment Regimens Are Not Readily Applicable

Achievement of levels of blood glucose necessary to prevent or control disease progression and diabetic complications requires strict therapeutic regimens that are neither practical nor feasible for many patients and their families. Intensive therapy requires multiple daily injections of insulin and frequent monitoring of blood glucose. Adherence to stringent dietary practices coupled with the necessity of coordinating food intake and insulin administration is difficult, especially for children and adolescents. No wonder most patients do not use the tools and do not follow the strict regimens of intensive treatment necessary to achieve tight glucose control.

Intensive Therapy Regimens Cause Frequent Episodes of Hypoglycemia

Current therapeutic regimens required to achieve normal or near-normal glycemia cause frequent episodes of hypoglycemia (more than a threefold increased risk of severe hypoglycemia in the DCCT). Hypoglycemia and the accompanying counterregulatory hormone response produced by iatrogenic hypoglycemia are often the major limiting factor in achieving tight glucose control. Frequent hypoglycemia causes hypoglycemic unawareness, a serious clinical problem (see Chap. 31). Avoidance of frequent hypoglycemia restores hypoglycemia awareness.²

Health Care Professionals' Experience with Intensive Glycemic Therapy Is Limited

Physicians and other health care professionals may not be adequately trained or experienced in the methods of intensive glycemic therapy. The integrated, multidisciplinary resources required for intensive therapy (e.g., dietitians, nurse educators, etc.) may not be available.

Insufficient Patient Knowledge about Diabetes and Involvement in Self-Management

Many patients do not fully understand their disease, the importance of tight glycemic control, and the principles of diet and exercise, nor are they sufficiently aware of the key role they must play in the treatment of their disease and attainment of good glycemic control.

Limited Awareness and Inadequate Support for Diabetes Care from the Health Care System

Intensive diabetes treatment is costly, beyond the capability of families with limited financial resources, and inadequately reimbursed. The critical need for intensive therapy is not always understood by those who administer health care systems.

CHANGES IN THERAPEUTIC APPROACHES FOR T1DM

New Prevention Approaches

Three targets provide the most obvious points for potential intervention in T1DM: genes, the immune system, and environmental factors.

Genes

The prevention, cure, and effective treatment of T1DM may ultimately come from genetic research that can identify the genes conferring disease susceptibility and delineate the mechanisms by which they produce their effects. This might lead to gene-based therapies. While the major human genes for T1DM could be identified and cloned within the relatively near future, elucidation of how they act to produce susceptibility to T1DM and development of gene-based therapy for this polygenic disease, if ever achievable, is unlikely to be accomplished in the near term.

Immune System

Immune modulation offers another approach for preventing T1DM. Primary prevention clinical trials are, or soon will be, under way to assess whether immune modulation can prevent T1DM in individuals at high risk (see Chap. 15). The NIH-sponsored Diabetes Prevention Trial—Type 1 Diabetes (DPT-1) recently reported that daily parenteral or oral insulin administration to induce immune tolerance to insulin in individuals at high risk did not prevent subsequent development of T1DM.³ Other means of modulating immune responses and preventing autoimmune β -cell destruction are being pursued, including antigen-, cytokine-, and monoclonal antibody-based interventions. However, applicability of results of trials in high-risk relatives to the general population in which 90% of new cases of T1DM occur is uncertain, and broader population-based trials will be necessary. Nevertheless, prevention of T1DM by immune intervention in high-risk relatives is certainly desirable and may be achievable.

Environment

A third approach to prevention of T1DM would be to block environmental factors that activate or interact with T1DM susceptibility genes. Unfortunately, the offending environmental factors, whether infectious (e.g., viruses), toxins, dietary, or otherwise, are unknown.

New Treatment Options

Noninjectable Routes of Insulin Administration

Oral Insulin

Proteolytic degradation and poor absorption have so far made efforts to produce an orally bioavailable insulin unsuccessful. Efforts to expand oral delivery technologies for controlled release of molecules with predictable activity, e.g., polymer encapsulation and osmotic release technology, and to develop modified insulins that can be orally administered and reliably and reproducibly absorbed through the buccal or intestinal mucosa without loss of biological activity are ongoing, but far from being available for clinical application.^{4,5}

Orally Available Insulin Mimetics

An orally bioavailable fungal metabolite that activates the human insulin receptor tyrosine kinase, mimicking the action of insulin and lowering blood glucose in diabetic mice, has recently been discovered.⁶

Inhaled Insulin

Administration of insulin by the pulmonary route is currently in phase III clinical testing (see Chaps. 28 and 29),⁷ and may be available for treatment in the near future. Given its short duration of action, for type 1 diabetics inhaled insulin will have to be administered in combination with long- and/or intermediate-acting insulin to meet basal requirements and achieve 24-hour glycemic control. Issues of reproducible absorption, inhalation technology, powder versus liquid formulations, and long-term safety remain to be fully resolved.

Other Routes

While nasal and rectal routes of insulin administration appear unlikely to be successful, transdermal delivery by iontophoresis⁸ and via innovative implantation technology is being investigated.

New Injectable Insulin Formulations

Rapid-Onset Short-Acting Insulin

Rapid-onset short-acting lispro insulin has enabled better control of mealtime glucose and improved overall glycemic control in many with T1DM.⁹ Insulin aspart is a second rapid-onset short-acting insulin with similar activity to lispro insulin, available for treatment of diabetes.⁹ Both of these insulins will be increasingly utilized in clinical practice in the future.

Long-Acting Insulin

Insulin glargine, a new long-acting insulin analog, has become available for clinical use.⁹ This acidic insulin analog formulation cannot be mixed in the same syringe with other standard insulins. A second long-acting insulin analog, insulin detemir, is currently in clinical development.¹⁰ Clinical studies indicate that these insulin formulations provide relatively constant levels of basal insulin over 24 hours, and achieve better control of fasting glucose and HbA_{1c}.

levels with less nocturnal hypoglycemia than NPH insulin. They could enable significantly better glucose control when combined with injection or inhalation of other forms of insulin before meals.

Hepatospecific Insulin Analogs

A novel hepatospecific insulin analog, N^αB¹L-thyroxyl-insulin (B1-T4-Ins), has the potential to provide more physiologic insulin action than current insulin preparations.¹¹

Pancreatic Islet Transplantation

The use of islet allografts and novel combinations of immunosuppressive agents in T1DM has recently shown promise,¹² and multicenter trials are underway. A major hurdle is the lack of sufficient numbers of donor islets to meet the needs for successful islet transplantation. Pluripotential stem cells, and genetically engineered somatic cell lines may provide a source of cells and enable successful transplantation without requirement for lifelong immune suppression to prevent rejection and autoimmune destruction of transplanted cells (see Chap. 56). The early promise of xenograft transplanted pig islets appears to be fading because of concerns over possible transmission of infectious porcine microorganisms. Each of these approaches has significant hurdles to overcome before successful clinical application is possible.

The Artificial Pancreas

An implantable “artificial pancreas” that provides continuous, on-line measurement of blood glucose, activating a mechanical device (pump) to deliver insulin directly to the liver, with or without glucagon, would permit more physiologic and readily applicable replacement of insulin (see Chaps. 14 and 29). Such a device is unlikely to become available in the near future. In the meantime, the two components of insulin delivery, the insulin pump and glucose sensor, will be used separately in the management of diabetes.

Implantable Insulin Pumps

Delivery systems that are implantable, able to be regulated with greater precision, and have more safety features are being developed and will be available in the not-too-distant future for treatment of T1DM and T2DM (see Chap. 29). Delivery of insulin directly to the liver, perhaps through an intraperitoneal route, if safe, would be more physiologic than delivery via the currently employed subcutaneous route. Adequate training of health care personnel and of patients and their families is essential for these devices to be used effectively and safely.

Noninvasive Glucose Sensors

The availability of accurate and sensitive, noninvasive glucose sensors for continuous measurement of blood glucose, displaying, downloading, and storing real-time blood glucose levels at a suitable interval and containing reliable hypoglycemia alert alarm systems, will greatly enhance glucose control and reduce the risk of hypoglycemia and hypoglycemia unawareness. Significant improvement in glucose-sensing technology can be anticipated in the not-too-distant future (see Chap. 29).

Control of Mealtime and Postprandial Glucose Levels

Achievement of normal or near-normal glycemia requires control of mealtime and postmeal blood glucose, not only fasting glucose.¹³ Treatment of T1DM will focus more on postprandial hyperglycemia than in the past, and will increasingly utilize premeal

administration of fast-onset short-acting insulins such as lispro, aspart, and possibly inhaled insulin. An analog of amylin, pramlintide, has been reported to reduce postprandial glucose in both T1DM and T2DM, and is currently being tested in humans.¹⁴ If results show adequate efficacy and safety, this drug may be useful, but the requirement for parenteral administration and the fact that it cannot be mixed with insulin in the same syringe will limit its clinical application.

Treatments to Induce Remission and Ameliorate Autoimmune β -Cell Destruction

Advances in understanding of the immunology of T1DM have laid the foundation for several clinical trials to assess whether immune modulation can prevent T1DM, or slow β -cell destruction and induce remission in newly diagnosed type 1 diabetics (see Chap. 15). As already discussed, the DPT-1 failed to demonstrate that daily parenteral insulin administration altered subsequent development of T1DM in individuals at high risk.³ Whether this failure means that insulin is not an important antigen in the autoimmune destruction of β cells in T1DM, or is the result of a flawed study design in the clinical trial, is not clear at this time. Other antigen-based approaches utilizing other antigens postulated to play a role in the autoimmune destruction of β cells in T1DM, including IA-2, IA-2b, heat shock proteins (e.g., hsp60, hsp70), and other immune targets (e.g., IL-4 and IL-2 related), are also being evaluated in human type 1 diabetic patients.

Studies in animal models of diabetes such as the nonobese diabetic (NOD) mouse demonstrate that several of these approaches can prevent development of insulinitis and diabetes, but the relevance and applicability to the prevention and treatment of human T1DM of these results in mouse type 1 diabetes must await the outcomes of ongoing and future human clinical trials of these agents and approaches. Encouragingly, initial clinical studies of a humanized anti-CD-3 monoclonal antibody have recently reported efficacy in inducing remission or slowing the rate of progression in newly diagnosed type 1 diabetic patients with sufficient remaining β -cell function.¹⁵

Methods to Stimulate β -Cell Regeneration and Growth and Inhibit β -Cell Apoptosis

Advances in β -cell biology could eventually lead to development of methods to stimulate β -cell regeneration in patients with diabetes (see Chap. 14). Factors such as glucagon-like peptide (GLP-1), exendin-4, insulin-like growth factor (IGF-1), nitric oxide, and certain β -cell transcription factors (e.g., pancreas duodenum homeobox-containing transcription factor-1 [PDX-1]) have been shown to possess stimulatory activity for islet cell growth, but their specificity is unknown.^{16,17} In T1DM this approach will have to be coupled with immune suppression to prevent autoimmune destruction of β cells; it may, therefore, be more feasible in patients with T2DM. Advances in this area may enable stimulation of β -cell growth and help to ensure an adequate supply for islet transplantation.

T2DM: TREATMENT SHORTCOMINGS

Limitations in Understanding the Causes and Pathophysiology of T2DM

More effective and safer therapies directed towards specific underlying defects require greater knowledge about the disease gained through intensified biomedical and behavioral research.

Limitations of Existing Oral Hypoglycemic Agents

Current oral agents, at least as currently utilized by most patients, are limited in their ability to achieve normal or near-normal glycemia in most type 2 diabetic patients. Significant side effects such as hypoglycemia, gastrointestinal dysfunction, fluid retention, edema, liver failure, and lactic acidosis compromise proper dosing and limit patient compliance. Both more effective and safer drugs and better use of existing agents are required.

Therapy May Be Initiated Too Late

Treatment of T2DM is usually begun after the disease has progressed significantly, perhaps to the point where intervention can have only limited effect. Numerous studies, most recently the UKPDS,¹⁸ have established that the complications of diabetes often begin before clinical diagnosis of the disease, and before the development of fasting hyperglycemia and elevated HbA_{1c}. Epidemiologic evidence from the UKPDS indicates that increased risk for micro- and macrovascular disease begins at HbA_{1c} levels of 6.5%.

Both underlying defects of T2DM, insulin resistance and defective insulin secretion, exist before fasting hyperglycemia occurs. HbA_{1c} becomes elevated, diagnosis of diabetes is made, and therapy is initiated. Both defects predict subsequent development of overt disease and may be risk factors for complications,¹⁹ and both may be targets for earlier therapeutic intervention. For example, acute-phase insulin secretion is commonly lost at fasting glucose levels between 6.1 and 6.5 mmol/L.²⁰ Loss of acute phase insulin secretion in response to a meal causes mealtime and postprandial hyperglycemia, reactive hyperinsulinemia, and hypoglycemia, often the earliest clinically detectable abnormalities of T2DM. Isolated mealtime hyperglycemia commonly exists in individuals with normal fasting glucose levels, especially in older adults who make up such a large proportion of the type 2 diabetic population.²¹⁻²³ Restoration of early insulin levels has been reported to improve glucose tolerance in type 2 diabetics,¹ yet treatment usually does not begin until the diabetes is diagnosed by fasting hyperglycemia.

Clearly, T2DM needs to be treated earlier, perhaps even before development of fasting hyperglycemia of 7.0 mmol/L as defined by current diagnostic criteria, and the current therapeutic target of HbA_{1c} of 7%. Further downward revision of the new diagnostic criteria established in 1997²⁴ may be necessary to help address this shortcoming. The results of the recently-concluded NIH-sponsored Diabetes Prevention Program (DPP) strongly support this view.²⁵ This study demonstrated that in prediabetic patients at high risk for developing T2DM (patients with impaired glucose tolerance), treatment intervention to improve glucose control can significantly reduce progression to overt clinical diabetes.

Therapy Is Too Narrowly Focused

Although, as just described, insulin resistance and defective insulin secretion exist early in the course of the disease, current treatment approaches usually address only one of these two abnormalities. Treatment is likely to be more effective if both defects, insulin resistance and impaired insulin secretion, are addressed, and in the view of this author the earlier the better.

Additionally, current therapy is often focused on managing fasting hyperglycemia and on targeting this endpoint as a measure of adequate glycemic control. Mealtime and postprandial glycemia

are often ignored, yet they contribute to overall 24-hour hyperglycemia,^{13,23} worsen the underlying defects of insulin secretion and action, and may increase risk of complications. The newly established treatment targets focus on fasting plasma glucose levels and give scant attention to the importance of reducing postprandial hyperglycemia.^{24,26} As an additional consideration, several recent epidemiologic studies suggest that mealtime and postprandial blood glucose levels are independent risk factors for cardiovascular disease and mortality.^{21,27} It is to be emphasized, however, that controlled clinical studies are needed to confirm this epidemiologic association.

Future treatment of T2DM will be more broadly focused, to address both impaired insulin action and insulin secretion, and to reduce both fasting *and* postprandial hyperglycemia.

Therapy Is Insufficiently Aggressive

Blood glucose levels are often allowed to remain too high for too long because patients are asymptomatic. Combination therapy with oral agents and addition of, or switching to, insulin is too often delayed until the disease is well advanced and glycemic control has deteriorated substantially. Efforts to control body weight, caloric intake, and physical activity are unfortunately often insufficient. Limitations in physician and allied health provider training and experience in the management of diabetes, and inadequate patient self-management, also contribute to the lack of more aggressive therapy.

Limited Awareness and Inadequate Support

T2DM does not receive the priority or attention from governments and the health care system that is required to contain and control what is rapidly becoming a worldwide pandemic (see Chap. 19). The magnitude, medical seriousness, and enormous economic cost of T2DM, as well as the extent to which socioeconomic factors and lifestyle contribute to the disease, remain unrecognized by these agencies. Governments must take the lead in sponsoring programs to enhance public awareness, and introduce public health programs to modify social, cultural, and lifestyle factors that contribute to T2DM.

CHANGES IN THERAPEUTIC APPROACHES FOR T2DM

Prevention

Theoretically, the most obvious means of preventing a large percentage of cases of T2DM is to prevent obesity. Indeed, clinical studies demonstrate that lifestyle intervention, including diet, reduced dietary fat intake, weight loss, and exercise, can significantly improve glucose tolerance in individuals at high risk for T2DM.^{25,28} However, societal attitudes, lifestyles, and nutrition tend to increase body weight and reduce physical activity, and preventing obesity or reducing body weight has proven difficult to accomplish and to maintain over time. Unless these lifestyle issues can be addressed more effectively, other interventions, primarily pharmacologic, will be required for the treatment of T2DM.

Prevention of T2DM may ultimately come from identification of the genes responsible for this form of the disease, and discovery of how they function to cause abnormalities of insulin secretion

and action. While the major human genes for T2DM might be identified and cloned within a few years, elucidation of how they act, and development of gene-based therapy for this polygenic disease, if ever achievable, is unlikely to be accomplished for many years.

New Treatment Options

A major shift in the approach to the treatment of T2DM is required. Current treatment is often too late, too little, and too narrowly focused. As discussed above, physician and allied health provider education and training must be increased so that diagnosis and therapy are more aggressive.

Earlier Diagnosis and Treatment

Increased efforts to detect and treat asymptomatic patients with fasting hyperglycemia, elevated HbA_{1c}, and postprandial hyperglycemia must become standard medical practice for the reasons discussed above. The recent downward revision of the fasting plasma glucose levels diagnostic of diabetes (i.e., ≥ 7 mmol/L [126 mg/dL]),²⁴ and treatment target levels to HbA_{1c} $\leq 7\%$, will enable earlier diagnosis and treatment, but these levels may not be low enough. The risk of complications appears to begin at significantly lower levels of fasting glucose and HbA_{1c}.^{18,24,26,27,29,30} Lower diagnostic criteria will enable earlier diagnosis and treatment of abnormalities that contribute to disease progression and complications, with the likelihood of more effective outcomes. However, documentation of such theoretical benefits through controlled clinical trials may be necessary to justify such a change in criteria.

The establishment of the categories of impaired glucose tolerance (IGT) and impaired fasting glucose (IFG) provides another opportunity for a major shift in the management of T2DM by potentially enabling earlier intervention.^{24,30} As discussed above, the DPP indicates that treatment during IGT, either with an effective program of diet and exercise or with the oral hypoglycemic drug metformin, can decrease the rate of progression of IGT to frank T2DM.²⁵ Thus, in all likelihood, future therapy may be directed toward treating individuals with IGT with lifestyle change programs (diet, weight control, and exercise) or with oral hypoglycemic agents capable of overcoming insulin resistance and/or restoring acute insulin secretion and lowering postprandial blood glucose. Drugs with proven safety and very low risk of hypoglycemia will have to be utilized. The thiazolidinediones may offer an opportunity to address the fundamental abnormality of insulin resistance. However, because of their potential for significant side effects (discussed later in this chapter), this class of drugs should not yet be utilized for early intervention in patients with IGT until adequate long-term safety has been clearly demonstrated. Though the DPP suggests that metformin may be sufficiently safe, at this time there is insufficient information from that study about patient tolerability of the drug. The newly emerging fast-acting nonsulfonylurea oral hypoglycemic drugs (discussed later in this chapter), which stimulate first-phase insulin secretion and reduce postprandial glucose, thereby addressing an early type 2 defect, might have a role in treatment of patients with IGT, provided that their long-term safety is established. At this time, lifestyle modification, including better nutrition, weight loss, and maintenance of normal body weight, and an appropriate program of physical activity, appears to be the only intervention with a sufficient level of established safety to be utilized in IGT.

Future therapy may also be directed toward treatment of patients with IFG, again with drugs with proven safety and a very low

risk of hypoglycemia. As currently defined, IFG identifies a different group of at-risk patients in the population than does IGT, with perhaps as little as 30–50% overlap with IGT.^{29,30} Thus if only VIFG is utilized to determine treatment intervention, large numbers of patients with IGT would go undetected. Since IGT is known to be a significant risk factor for development of cardiovascular disease, detection and treatment of IFG *alone*, without detection and treatment of IGT, would appear to be an undesirable strategy for early detection of risk and early intervention. For this reason, it has been suggested that the fasting glucose level diagnostic of IFG be lowered to ≤ 6 mmol/L (108 mg/dL) in order to identify individuals more similar to those with IGT with regard to risk of cardiovascular disease,²⁹ and that oral glucose tolerance testing continue, especially in high-risk patients.

Control of Mealtime and Postprandial Blood Glucose

Therapy of T2DM in the future should focus not only on controlling fasting blood glucose and HbA_{1c}, but also on control of mealtime and postmeal glucose levels. In some type 2 diabetic patients, reduction of postprandial glucose levels has been shown to contribute to lowering HbA_{1c} at least as much and possibly to a greater degree than reduction of fasting glucose.^{31,32} In the future, mealtime and postprandial hyperglycemia may be treated *before fasting hyperglycemia occurs* (i.e., before fasting glucose reaches >7 mmol/L or 125 mg/dL). For example, patients with elevated postprandial glucose levels, but normal fasting glucose, may be treated with oral hypoglycemic agents capable of stimulating early insulin secretion, and lowering postmeal hyperglycemia (discussed later in this chapter). Easier methods to detect patients with postprandial hyperglycemia and to assess efficacy of treatment in a clinical setting are required. Screening of patients at high risk for developing T2DM with oral glucose tolerance tests is cumbersome, but may be desirable. Appropriate targets for postprandial glucose levels will have to be established. Current epidemiologic data on increased cardiovascular risk suggest that a 2-hour postprandial plasma glucose of 11 mmol/L is too high, and that <10 mmol/L or 180 mg/dL may be more appropriate.²⁷

Combination Therapy

It is unlikely that a single oral agent will successfully control 24-hour blood glucose levels for very long in most patients with T2DM. Combinations of two or more drugs (see Chaps. 30 and 32) that target *both* underlying defects of T2DM, impaired insulin secretion and action, and *both* fasting and postprandial hyperglycemia, should begin earlier in the course of the disease, perhaps as early as at the time of diagnosis, in order to achieve better overall glycemic control, and perhaps more successfully modify the disease process. At times, three oral hypoglycemic agents or two oral agents and insulin may have to be utilized. Earlier addition or switch to insulin may be required in certain patients in order to more aggressively control blood glucose.

Control of Nonglucose Risk Factors

In addition to control of blood glucose, restoration of normal blood lipids, with statins and other hypolipidemic agents, and blood pressure control are essential in the management of T2DM. Better outcomes in the future demand more aggressive antihyperlipidemic and antihypertensive therapy, if necessary through the use of combinations of multiple drugs (see Chaps. 47 and 48).

New Orally Active Drugs To Stimulate Insulin Action and Overcome Insulin Resistance

Numerous targets for oral agents to enhance insulin action and increase glucose disposal exist, principally insulin-signaling proteins shown to cause insulin resistance in insulin-resistant tissues and laboratory animals (see Chaps. 5 and 22). Although as discussed in those chapters, defects have been demonstrated at several molecular sites in the insulin-signaling pathway, which, if any, account for the insulin-resistant state in human T2DM, and therefore might be viable targets for new drugs to overcome insulin resistance, is unknown. Given the high likelihood that there is a heterogeneity of defects responsible for insulin resistance in T2DM, that the relative contribution of each defect varies among type 2 patients, and that insulin resistance may be the result of additive effects of several interacting genetic and environmental (e.g., nutritional, obesity) factors on several insulin-signaling proteins, a single drug to prevent or correct all forms of insulin resistance in type 2 diabetic populations or even within individual type 2 patients is unlikely. Rather, multiple drugs targeted to different signaling molecules, at times in a "cocktail-like" form, together with lifestyle interventions, may have to be utilized.

Insulin Mimetics, Potentiators, and Sensitizers

Molecules are being developed to act at the insulin receptor or at one or more postreceptor signaling events to either mimic, potentiate, or sensitize cells to insulin action in order to overcome insulin resistance and promote glucose disposal. The orally active fungal derivative mimicking insulin action through phosphorylation of the tyrosine kinase domain of the insulin receptor described earlier is an example.⁶ A second orally active nonpeptide agent which induces insulin-dependent activation of the tyrosine kinase domain of the insulin receptor β subunit and reduces blood glucose in diabetic laboratory animals suggests another potentially useful approach for the treatment of insulin resistance in T2DM.³³ Inhibitors of protein tyrosine phosphatase, especially PTP-1B, are currently being evaluated in laboratory animals.³⁴ They are reported to enhance insulin sensitivity, increase glucose uptake, and improve glucose tolerance. It remains to be seen whether sufficient selectivity and specificity can be achieved with these agents to avoid unacceptable toxicity.

Other molecules involved in the cascade of signaling events that culminate in insulin's metabolic action are being explored as targets for development of drugs to enhance insulin action and increase glucose disposal (e.g., insulin receptor substrate 1 [IRS-1]), second messenger systems such as phosphatidylinositol-3-kinase (PI-3-kinase), glucose transport (stimulation of GLUT-4 translocation to the plasma membrane), and other downstream signaling proteins.^{34,35}

Agents Acting Through PPAR γ

The thiazolidenedione insulin sensitizers act through the nuclear receptor, peroxisome proliferator activated receptor (PPAR γ) (see Chap. 32). They have been welcomed as a step forward in the management of T2DM because they enhance insulin sensitivity and increase glucose disposal, thus addressing insulin resistance, a fundamental abnormality in T2DM. However, because of severe liver toxicity, the first thiazolidenedione, troglitazone, has been withdrawn. Rosiglitazone and pioglitazone, the most recently developed drugs in the class, appear not to cause hepatotoxicity, but more clinical experience is required to be certain of their safety in this regard. On the other hand, both of these drugs can cause significant weight

gain, fluid retention, and edema, side effects that may limit their long-term usefulness. Additional thiazolidenedione analogs and nonthiazolidenedione drugs acting through PPAR γ with greater efficacy and safety are being sought and developed.^{36,37} In this regard, RXR agonists, which act through the PPAR γ -RXR heterodimer to increase insulin action and decrease blood glucose, also appear to be associated with significant toxicity, raising doubts about the long-term clinical usefulness of drugs acting on this target.

The recent observations that a PPAR γ knockout mouse model with PPAR γ deficiency is associated with increased insulin sensitivity,³⁸ and that a RXR antagonist reduces blood glucose in diabetic laboratory animals,³⁹ suggests another PPAR γ -RXR-based approach to developing insulin sensitizers. Several dual PPAR agonists, targeting both PPAR γ for glucose control and PPAR α for control of lipids are currently in clinical development.³⁹ If they are to be successful, it will be necessary to achieve the correct balance of PPAR γ and PPAR α activity.

β_3 -Adrenergic Receptor Agonists

β_3 -Adrenergic receptor agonists, which increase energy expenditure through increased thermogenesis in brown and lipolysis in white adipose tissue, and which increase insulin-stimulated glucose disposal and improve glucose tolerance in laboratory animals and humans,⁴¹ have so far been hampered by having modest hypoglycemic efficacy, insufficient selectivity, and significant side effects. These drawbacks must be overcome for this approach to be of use in the management of T2DM.

Inhibition of Fatty Acid Oxidation

It is highly likely that all agents focused on fatty acid oxidation inhibition will have the same unacceptable toxicities as previously developed and tested drugs.⁴²

Inhibition of Hepatic Gluconeogenesis and Hepatic Glucose Output

Inhibitors of gluconeogenic enzymes such as PEPCK and F1-6 bisphosphonate have been associated with unacceptable toxicity, especially serious hypoglycemia. New avenues of research in this area include: (1) overexpression of the bifunctional hepatic enzyme 6-phosphofructo-2-kinase/fructose-2-6-bisphosphonate, thereby decreasing gluconeogenesis and increasing glycolysis,⁴³ and (2) modulation of hepatic nuclear transcription factors that regulate gluconeogenic enzymes,³⁴ an indirect approach that may lead to therapeutic agents to inhibit gluconeogenesis that are safer than those directly targeting gluconeogenic enzymes in the liver.

Stimulation of Glycogen Synthesis

The demonstration that reduced levels of hepatic glycogen contribute to dysregulated hepatic glucose production in T2DM has led to efforts to seek drugs that increase the capacity of the liver for glycogenesis. Focus has been on molecules that enhance the activity of glycogen synthase, hepatic glucokinase, and protein phosphatase-1 (PP-1). In laboratory animals these approaches have been associated with increased hepatic glucose disposal. Hepatic overexpression of glucokinase reduces blood glucose concentration in diabetic mice, but increases plasma free fatty acids and triglycerides. Increasing expression of other regulated members of the family of glycogen-targeting subunits of hepatic PP-1 to enhance glucose disposal and glycogen storage in diabetic patients, thereby lowering blood glucose levels, are being pursued.⁴⁴

Growth Hormone and IGF-1

Fragments of growth hormone (e.g., hGH 6-13) have been shown to increase insulin action and improve glucose tolerance in laboratory animals, and several analogs are in preclinical development.⁴⁵ Adequate oral bioavailability is uncertain. IGF-1 has been demonstrated to substitute for insulin action in rodents and humans, and has been explored for treatment of T2DM.⁴⁶ IGF-1 has been associated with side effects, but they can be reduced by combination with IGF-BP3. Inhibition of growth hormone secretion by IGF-1 and somatostatin analogs are also being evaluated. To date they have met with limited success. Inhibition of growth hormone may promote obesity, and thus on balance may be undesirable.

Glucagon Inhibition

Inhibitors of pancreatic glucagon secretion (e.g., glucagon-like peptide [GLP-1], somatostatin, exendin-4^{47,48}), and of glucagon action in the liver (e.g., glucagon receptor antagonists⁴⁹), have been shown to reduce blood glucose in laboratory animals. GLP-1 and synthetic exendin-4 have to be made either orally bioavailable or long-acting for large-scale application to treatment of T2DM. Such agents are unlikely to have a major impact on glycemic control unless used in combination with other hypoglycemic agents, but they may have the desirable effect of reducing insulin dosage.

Miscellaneous Approaches To Overcome

Insulin Resistance

Among various approaches currently being pursued are TNF α antagonists, resistin antagonists, and adenosine agonists.^{34,50}

Obesity-Related Approaches

The most obvious target for increasing insulin action in T2DM and returning blood glucose to normal or near-normal levels is reduction of excess adiposity. Indeed, numerous clinical studies demonstrate that lifestyle intervention can significantly improve glucose tolerance in individuals at high risk for T2DM.²⁸ Although recent progress in basic research has been great (see Chap. 23), many years will probably be required to develop effective drugs to prevent obesity or achieve and maintain weight loss. It is unlikely that a drug targeted to a single mechanism (e.g., leptin), a neuroendocrine peptide or receptor, or an uncoupling protein, will be successful given the redundancy and complexity of the process regulating eating behavior, energy homeostasis, and the adipose tissue mass. Rather, a combination of agents targeted to different sites in this process is likely to be required.

New Drugs To Stimulate Insulin Secretion

Several approaches to stimulate insulin secretion in a more physiologic manner are currently being pursued, and compounds are being tested in humans, including agents that stimulate first-phase insulin secretion, restore β -cell sensitivity to glucose, and stimulate or mimic gastrointestinal tract incretins such as GLP-1.

Nonsulfonylurea Insulin Secretagogues

A new class of nonsulfonylurea insulin secretagogues are now available for reducing mealtime and postprandial hyperglycemia in type 2 diabetics. This has not been achievable or achievable to only a limited degree by other oral hypoglycemic agents. Two drugs from this class are available: repaglinide, a benzoic acid derivative,⁵¹ and nateglinide, an amino acid derivative.³² A third agent, KAD 1229, is currently in development with only limited clinical experience at this time.⁵²

These drugs stimulate insulin secretion with a rapid onset and short duration of action, thereby reducing excessive mealtime glucose excursions that adversely affect overall glycemic control, and avoiding prolonged elevation of plasma insulin levels and exposure of tissues to hyperinsulinemia, in contrast to even the fast-acting sulfonylureas glipizide, glimepiride, and glipizide.

The major value of these short-acting nonsulfonylurea insulin secretagogues appears to be their stimulation of early insulin secretion after a meal and control of postprandial glucose, thereby offering the opportunity in certain subsets of type 2 patients to achieve better overall glycemic control and lower HbA_{1c} levels than is achievable with current drugs that focus only on fasting glucose. These drugs appear to be most useful when combined with drugs that enhance insulin action, and control fasting glucose (e.g., metformin or thiazolidinediones). Combination with sulfonylureas appears to have little or no added benefit. As monotherapy, these drugs may be useful for treatment of patients with T2DM who do not respond adequately to diet and exercise, suffer mild degrees of hyperglycemia (≤ 7 mm/L, ≤ 126 mg/dL), and are either early in the course of their disease, or are elderly, in whom hyperglycemia during (prandial) and after meals (postprandial) is the most pronounced glycemic abnormality, while fasting plasma glucose is either normal or mildly increased. For type 2 patients with more severe degrees of hyperglycemia, monotherapy with these agents is insufficient. To date, drugs of this class appear to be well tolerated and safe, particularly for avoiding hypoglycemia in patients with blood glucose levels below 180 mg/dL (10 mmol/L) and in older adults with T2DM. If proven safe with a low risk of hypoglycemia over the long term, these drugs may have a role in treatment of IGT.

Glucagon-Like Peptide-1 (GLP-1)

GLP-1 agonists and drugs that raise plasma levels of GLP-1 are being developed by several companies as a new approach for improving glycemic control (see Chap. 6).^{47,48,53-55} Because of its extremely short half-life and the need for parenteral administration, native GLP-1 itself is unlikely to become a therapeutic agent. Modified GLP-1 molecules with longer half-lives, requiring only once or twice daily injection, are also in clinical development and may soon be available for clinical practice. Since these agents must be administered parenterally on a daily basis, their applicability to the treatment of T2DM may be limited. An orally bioavailable inhibitor of DDP-IV,⁵⁵ the enzyme that degrades GLP-1, is currently in clinical development. This agent raises and maintains increased GLP-1 and GIP levels, increases insulin secretion and insulin action, inhibits glucagon secretion, reduces plasma glucose levels, and improves glucose tolerance in animal models of T2DM. Clinical trials have recently been initiated, and if efficacy is demonstrated, and inhibition of DDP-IV and prolonged elevation of GLP-1, GIP, and other peptides is safe, this could be an attractive drug for treatment of T2DM.

Exendin-4 is a 39-amino-acid peptide isolated from the saliva of the Gila monster. It has 53% sequence homology to GLP-1. A synthetic exendin-4 molecule, Ac2993, stimulates insulin secretion, reduces glucagon secretion, enhances insulin action, slows gastric emptying, and reduces plasma glucose in laboratory animals and humans.⁴⁸ Like GLP-1, this peptide must be administered parenterally, but unlike GLP-1 it has a prolonged half-life and activity. If ongoing clinical trials demonstrate adequate safety and efficacy in patients with T2DM, and an orally bioavailable formulation or a molecule with an extended half-life not requiring daily injection can be developed for large scale clinical application,

exendin-4 could have considerable value in the future treatment of T2DM.

If these drugs become available for clinical use, it is likely that they will be most useful in the treatment of T2DM as combinations of oral and parenteral forms, depending on the stage and severity of the disease, and when combined with other hypoglycemic agents.

Glucokinase

Efforts to restore or enhance β -cell sensitivity to glucose-stimulated insulin secretion by stimulation of β -cell-specific glucokinase activity are currently under investigation.⁵⁶ Even if a defect in glucokinase does not exist in the great majority of type 2 diabetics, increased β -cell sensitivity to glucose should be useful. While an agent enhancing glucokinase activity in both the β cell and the liver might appear to be attractive, a β -cell-specific drug may be preferable, given the finding that glucokinase stimulation in the liver of rodents is associated with elevated free fatty acids and triglycerides.⁴⁴

Reduction of Insulin Dosage and Hyperinsulinemia

It has been postulated that hyperinsulinemia contributes to the development of diabetic macrovascular disease. To minimize hyperinsulinemia, drugs that can be co-administered with insulin to reduce insulin dosage, such as the thiazolidinediones, will be increasingly utilized, if such use is not prevented by safety problems. Pramlintide, an analog of amylin, has been reported to reduce insulin dosage in both T1DM and T2DM, and is currently undergoing clinical testing.¹⁴ If safe and effective, this drug may be useful in insulin-treated patients with T1DM and T2DM, but the requirement for parenteral administration and the inability to mix it with insulin in the same syringe will limit its clinical application.

Other New Treatment Options

Methods to stimulate β -cell growth and regeneration, improved glucose sensors, the artificial pancreas, and islet transplantation, discussed earlier under the section on T1DM, are equally applicable to the management of T2DM, and offer opportunities for improved outcomes in the future.

COMPLICATIONS OF DIABETES

Therapies for Prevention and Treatment

Optimal Glycemic Control

Control of blood glucose to normal or near normal levels will continue to be the cornerstone of treatment to prevent and slow the rate of progression of diabetic complications. Methods for achieving this goal have been discussed earlier in this chapter.

Tissue-Specific Therapies

Identification of potential molecular and biochemical mechanisms by which hyperglycemia causes tissue damage gives rise to potential new therapeutic interventions targeted directly at diabetic complications (see Chaps. 1, 40–50, and 55). Many of these approaches are directed towards hyperglycemia-induced alterations in vascular endothelial cells. A few of them are described below.

Inhibitors of AGE, AGE-RAGE Interactions

Inhibitors of advanced glycation end-product (AGE) formation (see Chap. 42) (e.g., aminoguanidine⁵⁷) are being developed, but

they have encountered safety and efficacy problems. Inhibition of the AGE-RAGE (receptors for AGEs) interaction by blocking RAGE on endothelial, vascular smooth muscle, neural, mesangial, immune, and inflammatory cells appears more attractive and likely to be successful. Soluble RAGE (sRAGE) is reported to be effective against microvascular disease in laboratory animals, and sRAGE may provide a basis for developing an oral inhibitor of AGE-RAGE interaction or of AGE receptors.⁵⁸

Inhibition of Protein Kinase C (PKC)

PKC is believed to play an important role in the development of the vascular and neurologic complications of diabetes. At least one inhibitor of PKC is currently in phase III clinical studies for treatment of diabetic retinopathy⁵⁹ (see Chap. 41). Vitamin E and α -lipoic acid antioxidants have been shown to inhibit PKC.

Inhibitors of Aldose Reductase and Sorbitol Formation

Inhibitors of aldose reductase are in development by several companies for treatment of diabetic neuropathy (see Chaps. 44–46). Most appear to have had limited efficacy and unacceptable toxicity. A new generation of aldose reductase inhibitors is now in development, however at this time it is not known whether these will be more successful than their predecessors.

Inhibition of Angiogenic Growth Factors To Decrease the Formation of New Blood Vessels in Diabetic Retinopathy

A major focus of current drug discovery and development is inhibitors of vascular endothelial growth factor (VEGF) for the treatment of diabetic retinopathy.⁶⁰ Other targets receiving attention include growth hormone, TGF β , IGF-I, bFGF, angiotensin, integrins, and endothelin.⁶¹ Endothelin antagonism may also be applicable to the treatment of macrovascular disease.

Stimulation of Angiogenic Growth and Other Factors

Stimulation of these factors to increase formation of new blood vessels for treatment of coronary and peripheral vascular disease and to treat neuropathy is also under study.⁶² Gene therapy approaches to stimulate growth of new blood vessels are currently under investigation. Drugs that stimulate VEGF are also being sought for this indication, but these will have to be highly tissue-specific and selective, since systemic effects could adversely affect retinopathy by stimulating new retinal vessel growth. Agents that stimulate nerve growth factors (e.g., NGF, neurotrophins) are also being sought for treatment of diabetic neuropathy.⁶³

Antioxidants

Research to develop antioxidants to decrease oxidative stress and free radical formation in cells and tissues of the body is ongoing. A variety of drugs and natural substances such as vitamins C and E, α -lipoic acid, and γ -linolenic acid have been tested with minimal success.⁶⁴

Hypoglycemia

Pierre J. Lefèbvre

André J. Scheen

Strictly speaking, the definition of hypoglycemia is biochemical; i.e., hypoglycemia is present when the blood glucose level is lower than the lowest limit of normal physiologic fluctuations. Using a specific assay on whole blood, this limit is approximately 50 mg/dL or 2.8 mmol/L (45 mg/dL or 2.5 mmol/L for some authors). Such a limit is based on the fact that numerous studies have indicated that a blood glucose level of about 55 mg/dL (3 mmol/L) induces impairment of cognitive function in most subjects tested, suggesting that it may represent the threshold for brain damage (see below). During the first 48 hours of life, in the full-term neonate, this limit is 30 mg/dL or 1.7 mmol/L, whereas values below 20 mg/dL (1.1 mmol/L) are defined as hypoglycemia for small-for-date newborns. Thus, use of the term *hypoglycemia* to characterize a clinical symptomatologic entity is not entirely appropriate. Nevertheless, in clinical practice, one observes a constellation of symptoms and signs that point to the diagnosis.

CLINICAL SYMPTOMS SUGGESTING HYPOGLYCEMIA

In the adult, the symptoms of hypoglycemia^{1,2} are due to:

1. Adrenergic reaction, the symptoms of which predominate when the fall in blood glucose is rapid; they include pallor, sweating, tachycardia and palpitations, sensation of hunger, restlessness, and anxiety.
2. Cellular malnutrition at the neurological level, producing what Marks and Rose³ have called *neuroglycopenia*, or "the signs and symptoms which develop when the supply of metabolizable carbohydrates to the neuron is inadequate for normal function." The symptoms are variable from one subject to another; they are generally more severe and occur at higher blood glucose levels in the elderly than in the young. These symptoms, which are more prominent when hypoglycemia develops slowly, include fatigue, irritability, headache, loss of concentration, somnolence, psychiatric or visual disorders (e.g., diplopia), transient sensory or motor defects, confusion, convulsions, and coma. If hypoglycemia remains untreated, death may supervene. Angina pectoris (and very rarely actual myocardial infarction) may also result from cellular malnutrition. In a given patient, the symptoms associated with hypoglycemia tend to be repetitive and stereotyped. Weinger and associates⁴ have reported that many patients make clinically serious errors

in glucose estimation and use symptoms that do not differentiate hyperglycemia from hypoglycemia.

It should be noted that recurrent episodes of severe hypoglycemia may result in cumulative and permanent cognitive impairment,^{5,6} although this has recently been challenged.⁷ Furthermore, repetitive episodes of hypoglycemia, particularly at night, have been recognized to induce *hypoglycemia unawareness*, a situation in which the patient with diabetes does not experience appropriate autonomic warning symptoms before development of neuroglycopenia.⁸ Several recent studies have shown that glycemic thresholds for hypoglycemic cognitive dysfunction, like those for autonomic and symptomatic responses to hypoglycemia, shift to lower plasma glucose levels after recent antecedent hypoglycemia in patients with type 1 diabetes (T1DM).⁹⁻¹¹ Interestingly, antecedent hypoglycemia also induces blunting of the hormonal and metabolic responses to physical exercise.¹²

In the newborn, the symptoms of hypoglycemia may be more difficult to recognize. They include a high-pitched cry, skin pallor or cyanosis, respiratory distress, apnea, sluggishness, irritability, hypotonia, or intermittent twitching and occasionally grand mal seizures.³ In the older child, the following symptoms may arouse suspicion: frequent yawning, episodic staring, bizarre behavior, twitching, pallor, remoteness, paresthesias, visual disturbances, and loss of concentration. These symptoms are often mistaken for petit mal attacks.

ETIOLOGY OF HYPOGLYCEMIA

There are two principal forms of hypoglycemia: exogenous hypoglycemia attributable to injection or ingestion of a hypoglycemic compound, and endogenous hypoglycemia, which will be considered later (Table 58-1).

Exogenous Hypoglycemia

Insulin

Insulin is by far the most frequent cause of hypoglycemia, and it can occur in both diabetic and nondiabetic patients. The EURO-DIAB IDDM Complications Study indicated that the proportion of patients with one or more severe hypoglycemic attacks in 1 year averaged 32%, with a minimum of 12% in one center and as many as 48% in another.¹³ Predictors of severe hypoglycemia in patients

TABLE 58-1. Etiology of Hypoglycemia

<i>Exogenous Hypoglycemia</i>	<i>Endogenous Hypoglycemia</i>	<i>Functional Hypoglycemias</i>
Insulin	Organic hypoglycemias	Alimentary hypoglycemia
Oral antidiabetic agents	Insulinomas and related disorders	Spontaneous reactive hypoglycemia
Alcohol	Insulinoma	Alcohol-promoted reactive hypoglycemia
Other exogenous agents	Nesidioblastosis and β -cell hyperplasia	Posthyperalimentation hypoglycemia
Salicylates	Extrapaneatic neoplasms	Endocrine deficiency states
Hypoglycins	Inborn errors of metabolism	Hypoglycemia due to glucocorticoid deficiency
Pentamidine	Hereditary fructose intolerance	Hypoglycemia in GH deficiency
Perhexilin	Fructose-1,6-diphosphatase deficiency	Hypoglycemia and catecholamine deficiency
Quinine	Galactosemia	Hypoglycemia and glucagon deficiency
β -Receptor blocking drugs	Phosphoenolpyruvate carboxykinase deficiency	Severe liver deficiency
Other drugs	Inborn errors in glycogen metabolism	Profound malnutrition
		Prolonged muscular exercise
		Autoimmune insulin syndrome
		Antibodies against the insulin receptor
		Functional or transient hypoglycemia in infancy
		Transient neonatal hypoglycemia
		Infants of diabetic mothers
		Erythroblastosis fetalis
		Leucine-induced hypoglycemia
		Ketotic hypoglycemia
		Maple syrup urine disease
		Adrenal hyporesponsiveness

with T1DM have been described by Gold and colleagues¹⁴ and Mülhauser and coworkers.¹⁵

In diabetic patients, hypoglycemia may result from administration of an overdose or from the concomitant administration of drugs that when given alone favor hypoglycemia. The overdose may be absolute or relative: mistake in the evaluation of the dose, injection repeated by mistake (by the patient or by the nursing staff), poor comprehension of medical instructions, lack of sufficient food intake (gastrointestinal problems, ritual or presurgery fast, etc.), unusual physical exercise, or abrupt decrease in the insulin requirements (immediate postpartum, certain cases of insulin resistance). Hypoglycemia unawareness has been claimed to be more frequent with human than with porcine insulin, but this has not been confirmed in subsequent studies.

To prevent excessive insulin-induced decrements in plasma glucose levels, the glucoregulatory hierarchy is as follows: (1) The primary counterregulatory role is played by *glucagon*, which stimulates hepatic glucose production; (2) *epinephrine*, which is not normally critical, but plays an essential role when glucagon is deficient, acts by reducing glucose utilization and stimulating hepatic glucose production; (3) *growth hormone* and *cortisol* contribute late in glucose recovery from prolonged hypoglycemia by increasing rates of glucose production and decreasing rates of glucose utilization; and (4) *hepatic glucose autoregulation*, independent of hormonal and neural regulation, which is demonstrable only during very severe hypoglycemia.¹⁶ The major role of the hypothalamus in mediating the counterregulatory response to hypoglycemia has been evidenced by the demonstration that such counterregulation was completely lost in a patient with hypothalamic sarcoid infiltration.¹⁷ Recent studies have shown that the counterregulatory response of type 1 diabetic women is decreased compared to that of type 1 diabetic men.¹⁸ Furthermore, the epinephrine response to hypoglycemia is markedly reduced during sleep.¹⁹ Finally, the counterregulatory response to the short-acting insulin analogue lispro has been found to be identical to that to human or porcine insulin.²⁰ It is now well demonstrated that glucagon secretory responses to plasma glucose decrements become deficient early in

the course of T1DM in the vast majority of patients, often within the few years following diagnosis. However, because epinephrine compensates for deficient glucagon secretion, counterregulation is adequate in many of these patients. Nevertheless, the epinephrine secretory response to plasma glucose decrements becomes deficient typically later in the course of the disease and this defect has generally been attributed to autonomic neuropathy. Those patients with combined glucagon and epinephrine deficiencies are at substantially increased risk of severe hypoglycemia, at least during intensive therapy.

Particularly severe hypoglycemia has been reported in some patients treated with continuous subcutaneous insulin infusion (CSII). During CSII, the incidence of severe hypoglycemic episodes ranges between 0.1 and 1.2 per patient per year. As shown by White and associates,²¹ patients having defective counterregulatory responses to insulin-induced hypoglycemia have a 20- to 25-fold greater chance of developing severe hypoglycemia than those who counterregulate correctly. In the Diabetes Control and Complications Trial (DCCT), the incidence of severe hypoglycemia was approximately three times higher in the intensive therapy group than in the conventional-therapy group.²² In fact, in the intensive therapy group, there were 62 hypoglycemic episodes per 100 patient-years in which assistance was required in the provision of treatment, as compared to 19 such episodes per 100 patient-years in the conventional therapy group. This included 16 and 5 episodes of coma or seizure per 100 patient-years in the respective groups.

A recent meta-analysis of the effect of insulin lispro on severe hypoglycemia in patients with T1DM has shown a slight but significant reduction in the incidence of severe hypoglycemia as compared with regular insulin therapy; out of 2327 patients receiving lispro, 72 (3.1%) had a total of 102 severe episodes, compared to a group of 2339 receiving regular human insulin in which 102 (4.4%) had a total of 131 episodes ($p = 0.024$).²³

The hypoglycemic effect of insulin can be exacerbated by the simultaneous ingestion of ethanol (see later) or of numerous drugs. These include sulfonylureas, biguanides, nonselective β -receptor blocking agents like propranolol, monoamine oxidase inhibitors,

ACE inhibitors, salicylates, and tetracyclines. When β -receptor blockade is needed in diabetics for cardiocirculatory reasons, selective β_1 -receptor blocking agents like atenolol, metoprolol, bisoprolol, or acebutolol should be used. Potentiation of the hypoglycemic effect of insulin in diabetic patients can be observed in coexisting adrenocortical or pituitary insufficiency. Pituitary ablation, irradiation, and cryoablation have been used in the past for the treatment of advanced diabetic retinopathy. These procedures always result in increased insulin sensitivity and a potential danger of hypoglycemia.

In nondiabetic as well as in diabetic patients, insulin has been used for homicidal or suicidal purposes (reviewed in Marks and Teale²⁴). Severe unexplained hypoglycemia in a nondiabetic individual should always raise the possibility of exogenous insulin administration, either suicidal or criminal. Such cases are more frequently encountered in the medical milieu or in the family or neighborhood of diabetics. Inadvertent insulin administration to a hospitalized nondiabetic patient has also been reported. In psychiatric patients, intentionally induced insulin shock therapy sometimes leads to prolonged hypoglycemia and irreversible brain damage. Factitious hypoglycemia due to clandestine self-administration of insulin must always be considered in the differential diagnosis of hypoglycemia. Again, this situation is more frequently encountered in the relatives of diabetic patients, in the medical or paramedical professions, and sometimes in diabetic patients themselves.

Oral Antidiabetic Agents

These drugs not infrequently cause hypoglycemia in diabetic patients, particularly if used inappropriately. Hypoglycemia is observed more frequently in patients taking long-acting sulfonylureas such as chlorpropamide and glibenclamide²⁵ or in those taking the highly potent sulfonylureas such as glibenclamide, glyburide, or glipizide. Overdose or insufficient food intake often explains the occurrence of hypoglycemia. Patients with renal or hepatic insufficiency, which may interfere with excretion or metabolism (or both) of these drugs, are especially susceptible to hypoglycemia.

As with insulin, oral antidiabetic agents can be involved in the pathogenesis of hypoglycemia in nondiabetic patients through inadvertent administration, accidental ingestion (mainly in children), a suicide attempt, and clandestine ingestion (a variety of factitious hypoglycemia). Over recent years, potentiation of the hypoglycemic properties of sulfonylureas by alcohol or by various drugs has been recognized as a major source of hypoglycemia. Table 58-2 summarizes the various mechanisms involved, and Table 58-3 gives the pharmacologic classes of the drugs to consider.²⁶ In contrast to sulfonylureas, biguanides, when taken alone, essentially never cause hypoglycemia, except in the case of simultaneous prolonged fasting or severe caloric and carbohydrate restriction. Hypo-

TABLE 58-3. List of Main Drugs Capable of Inducing Hypoglycemic Episodes in Diabetic Patients Treated with Sulfonylureas

<i>Antibacterial sulfonamides:</i> sulfaphenazole, sulfamethoxime, sulfadimidine, sulfathiazole, sulfadiazone, sulfisoxazole, etc.
<i>Analgesics and anti-inflammatory drugs:</i> salicylates, phenylbutazone, oxyphenbutazone
<i>Drugs affecting plasma lipoprotein concentration:</i> clofibrate, fenofibrate
<i>Antibiotics:</i> chloramphenicol, novobiocin, tetracyclines, doxycycline
<i>Miscellaneous:</i> allopurinol, probenecid, phenylamidol, monoamine oxidase inhibitors, tromethamine, isoniazid, sulfinpyrazone, angiotensin-converting enzyme (ACE) inhibitors

glycemia is not caused by α -glucosidase inhibitors or glitazones used in monotherapy.

Alcohol

The ability of ethanol to induce hypoglycemia has long been recognized. In this section we will deal only with alcohol-induced fasting hypoglycemia; the so-called alcohol-promoted reactive hypoglycemia will be discussed later, in the section on functional hypoglycemias. Alcohol-induced fasting hypoglycemia characteristically develops in chronically malnourished or more acutely food-deprived individuals within 6–36 hours of ingesting a moderate to large amount of alcohol. Alcohol-induced fasting hypoglycemia results essentially from decreased hepatic glucose output due to impairment of liver gluconeogenesis, but other mechanisms such as ethanol-induced abnormalities in hypothalamic-pituitary-adrenal or hypothalamic-pituitary growth hormone secretions may be involved. Accidental ingestion of alcohol in children can also lead to severe hypoglycemia. As seen previously, alcohol also markedly potentiates the hypoglycemic effects of insulin and oral antidiabetic agents. According to Marks,²⁷ alcohol-induced fasting hypoglycemia often develops slowly and insidiously in the comatose person who has overindulged, and probably accounts for at least some of the deaths that occur in vagrants and others who are put unsupervised into police cells to sober up overnight and are found dead in the morning.

Other Exogenous Agents

Numerous other exogenous agents or drugs may cause hypoglycemia (see review in Marks and Teale²⁸).

Salicylates

Salicylic acid, salicylate, and their derivatives have been recognized as potential hypoglycemic agents for more than 100 years, and the beneficial effect of sodium salicylate in diabetes mellitus was reported in the nineteenth-century pharmacopeia. The mechanism of their hypoglycemic properties is not fully elucidated, but involves increased utilization of glucose by peripheral tissues and reduction of gluconeogenesis. In salicylate poisoning, particularly in children below the age of 2 years, hypoglycemia may be observed together with the more common alteration of the acid-base equilibrium: initial respiratory alkalosis due to stimulation of the respiratory center and subsequent metabolic acidosis caused by the drug itself. Children with fever and dehydration are particularly prone to intoxication from relatively small doses of salicylate. Salicylates potentiate the hypoglycemic effects of sulfonylureas. Aspirin can also induce hypoglycemia in adults, mainly under exceptional circumstances such as when large doses are given to patients with renal failure.

TABLE 58-2. Mechanisms by which Various Drugs Increase the Hypoglycemic Effect of Sulfonylureas

-
- | |
|---|
| 1. Increase in half-life due to inhibition of metabolism or excretion rate: ethanol, phenylbutazone, coumarin anticoagulants, chloramphenicol, doxycycline, antibacterial sulfonamides, phenylamidol, allopurinol |
| 2. Competition for albumin binding sites: phenylbutazone, salicylates, antibacterial sulfonamides |
| 3. Inhibition of gluconeogenesis, increase in glucose oxidation, or stimulation of insulin secretion: ethanol, β -adrenergic drugs, monoamine oxidase inhibitors, tranlycypromine, tromethamine. |
-

Hypoglycins

Hypoglycins are compounds found in the unripe tropical fruit *Blighia sapida*. They are responsible for the Jamaican vomiting sickness, a syndrome characterized by vomiting, shock, and hypoglycemic coma; death is common. Hypoglycemia results from inhibition of liver gluconeogenesis and increased peripheral glucose utilization; these alterations apparently result from inhibition of long-chain fatty acid oxidation caused by the toxic agent.

Quinine

Severe hypoglycemia and hyperinsulinemia can occur in patients with *Plasmodium falciparum* malaria treated with intravenous quinine. The hypoglycemia is due to massive stimulation of insulin by quinine. The risk of hypoglycemia is particularly high in patients with cerebral malaria. These patients require frequent blood glucose monitoring, and massive intravenous glucose infusion.

β -Receptor Blocking Agents

As already mentioned, nonselective β -receptor blocking agents potentiate the hypoglycemic action of both insulin and sulfonylurea-type drugs. Furthermore, β -blockers may favor hypoglycemia by their inhibitory effect on adipose tissue lipolysis, which provides alternative fuels when the glucose concentration is low. Consequently, hypoglycemia due to β -blockers has been observed in young children, usually after a 6- to 10-hour fast. Maternal therapy with β -blockers may affect the fetus and exaggerate neonatal hypoglycemia.

Pentamidine

Used in the treatment of *Pneumocystis carinii* infection, an opportunistic infection frequently seen in patients with the acquired immunodeficiency syndrome (AIDS), pentamidine has been reported to induce massive cytolysis of the β cells of the islets of Langerhans, a process leading to temporary hyperinsulinemia and hypoglycemia followed by insulinopenic diabetes.

Other Drugs

Ouabain, mebendazole, isoproterenol, tris(hydroxymethyl)aminomethane (THAM), mesoxalate, disopyramide, tranlycypromine, and possibly monoamine oxidase inhibitors may cause hypoglycemia by stimulating insulin release. Potassium para-aminobenzoate, haloperidol, propoxyphene, anabolic steroids, perhexilin, and guanethidine have been incriminated as possible causes of hypoglycemia through unknown mechanisms. Clofibrate and angiotensin-converting enzyme inhibitors have been reported to potentiate the hypoglycemic properties of oral antidiabetic agents.

Endogenous Hypoglycemia

Endogenous hypoglycemia may be organic (insulinoma, extrapancreatic neoplasms, or due to inborn errors of metabolism) or functional.

Organic Hypoglycemia

Insulinomas and Related Disorders

Insulinoma Insulinomas are uncommon neoplasms that derive from the β cells of the islets of Langerhans.^{29,30} The majority of these tumors, 68–85% according to published series, are single, benign adenomas; multiple adenomas or scattered microadenomas

are observed in 10–19% of the cases; and islet cell carcinomas are less frequent (2–11% of cases). Islet cell adenoma can be part of the pluriglandular syndrome. It has sometimes been reported to coexist with the pancreatic gastrinoma of the Zollinger-Ellison syndrome.

Nesidioblastosis and β -Cell Hyperplasia Nesidioblastosis, now called persistent hyperinsulinemic hypoglycemia of infancy (PHHI), is a rare disease leading to persistent hypoglycemia of infancy. It is histologically characterized by the budding off from duct epithelium of endocrine cells and by the presence in the pancreas of microadenomas. The onset of symptoms of β -cell hyperplasia may occur during the first days of life, but most commonly appears within the first 6 months. A few cases with symptoms beginning later than 1 year of age have been reported. The group of Saudubray in Paris³¹ has recently reported the features of 52 neonates with hyperinsulinism. Thirty neonates had diffuse β -cell hyperfunction, and 22 had focal adenomatous islet cell hyperplasia. Among the latter, the lesions were in the head of the pancreas in nine, the isthmus in three, the body in eight, and the tail in two. Partial pancreatectomy has been successful in curing the 19 out of the 22 neonates in whom this procedure has been attempted. Recent studies (reviewed in Thomas³²) have shown that congenital hyperinsulinism with focal or diffuse nesidioblastosis can be associated with several mutations affecting the β cell, such as the genes encoding for the sulfonylurea receptor, glucokinase, or glutamate dehydrogenase.

Extrapancreatic Neoplasms

In a review on tumor hypoglycemia, Kahn³³ stated that it was likely that non-islet cell tumors would be second only to islet cell tumors as a cause of chronic fasting hypoglycemia in the adult. Most of these neoplasms are large and present as masses in the mediastinum or the retroperitoneal space. According to Kahn,³³ 45% of the tumors have a mesenchymal origin (Doege-Potter syndrome), 23% are hepatomas (Nadler-Wolfer-Elliott syndrome), 10% are adrenocortical carcinomas (Anderson's syndrome), 8% are gastrointestinal tumors, 6% are lymphomas and leukemias, and 8% miscellaneous. Tumor hypoglycemia may occur in any age group, but is most common in adults between 40 and 70 years of age. The pathogenesis of the hypoglycemia in these tumors has been investigated by numerous groups in the past 20 years. Among the many theories that have been advanced to explain hypoglycemia, the production of an insulin-like substance has been considered likely by many investigators.^{34–36} A large form of insulin-like growth factor II, known as big IGF-II, has now been recognized to be responsible for the hypoglycemia by direct insulin-like action on nonhepatic tissues and the suppression of growth hormone secretion. Severe hypoglycemia caused by elevated IGF-II levels has also been reported in patients with acinar cell carcinoma of the pancreas,³⁷ solitary fibrous tumor of the pleura,³⁸ metastasis from a meningeal hemangiopericytoma,³⁹ and disseminated breast cancer.⁴⁰

Inborn Errors of Metabolism

One may argue against our choice to classify the inborn errors of metabolism as a cause of organic hypoglycemia. We certainly agree that some of these syndromes may also be considered as functional, e.g., when the symptoms occur only after ingestion of a single sugar, like fructose in the hereditary fructose intolerance syndrome. We think, however, that in many respects, these syndromes

characterized by a well-defined enzymatic defect, are really organic at the molecular level (see review in Lteif and Schwenk⁴¹).

Hereditary Fructose Intolerance (HFI)

Hereditary fructose intolerance, initially described as idiosyncratic to fructose, is a rare, autosomal recessively inherited, inborn error of metabolism characterized by an almost total lack of liver fructose-1-phosphate aldolase. Ingestion of fructose leads to intracellular accumulation of large amounts of fructose-1-phosphate. This in turn induces a decreased intracellular level of inorganic phosphorus, a derangement of the phosphate potential, and secondary enzyme inhibition by fructose-1-phosphate. These secondary enzymatic blocks are (1) an inhibition of further phosphorylation of fructose by fructokinase, leading to fructosemia and fructosuria; (2) an inhibition of liver phosphorylase; and (3) an inhibition of the remaining fructose-1,6-diphosphate liver aldolase activity. Inhibition of phosphorylase impairs glycogenolysis, a phenomenon that is favored by the low inorganic phosphorus concentrations. Inhibition of fructose-1,6-diphosphate liver aldolase, the enzyme that should perform the condensation of trioses to fructose-1,6-diphosphate, results in impairment of liver gluconeogenesis. Simultaneous inhibition of liver glycogenolysis and gluconeogenesis explains why fructose administration in HFI induces profound hypoglycemia, accompanied by convulsions and coma. Clinical manifestations at onset of symptoms can be rather unspecific, but usually the first signs of the disease start with exposure to saccharose. Besides hypoglycemia, the symptoms involve vomiting, poor weight gain, anorexia, various degrees of liver dysfunction, and perturbations of renal tubular function.

Fructose-1,6-Disphosphatase Deficiency

In this rare autosomal recessive disease, the lack of functioning fructose-1,6-phosphatase has little consequence as long as the liver glycogen stores are sufficient. When liver glycogen is depleted (e.g., after 12- to 24-hour fasting), hypoglycemia occurs, often accompanied by severe lactic acidosis. Hypoglycemia results from impairment in liver gluconeogenesis, and lactic acidosis is due to the transformation of various gluconeogenic precursors (glycerol, amino acids) or of fructose into lactic acid.

Galactosemia

Although hypoglycemia is the rule in hereditary fructose intolerance, it is less frequent in galactosemia. In this autosomal recessively transmitted disease, the missing enzyme is galactose-1-phosphate uridyl transferase, the enzyme permitting the transformation of galactose-1-phosphate into UDP-galactose. The major symptoms of galactosemia (jaundice, hepatomegaly, cirrhosis, kidney function alterations, cataracts, and mental retardation) seem to result from the accumulation of galactose-1-phosphate. Hypoglycemia, occurring after galactose exposure, would be the result of inhibition of liver glucose output due to inhibition of phosphoglucomutase by galactose-1-phosphate.

Phosphoenolpyruvate Carboxykinase Deficiency

Phosphoenolpyruvate carboxykinase (PEPCK) is a key enzyme in gluconeogenesis. This defect has been reported in a few cases of infants with severe fasting hypoglycemia.

Inborn Errors of Glycogen Metabolism

Among the 11 varieties of glycogen storage diseases now recognized, only some lead to hypoglycemia. Type I glycogen storage

disease, or von Gierke's disease, is due to a lack of liver glucose-6-phosphatase. Without this enzyme, the liver cannot produce glucose either from glycogenolysis or by gluconeogenesis (glucose-6-phosphate is an obligatory pathway in both processes). Unless carbohydrates are frequently given, severe hypoglycemia occurs, accompanied by excessive production of lactic acid. The clinical picture consists of small stature, puppet face, increased subcutaneous fat tissue, and massive hepatomegaly. Type II glycogen storage disease, or Pompe's disease, results from a deficiency in the lysosomal enzyme α -1,4-glucosidase, as demonstrated in 1963 by Hers. Lysosomal accumulation of glycogen causes cardiomegaly and heart failure, macroglossia, and hypotonia of voluntary muscles. This disease does not lead to hypoglycemia. Type III glycogen storage disease, or Forbe's disease, is characterized by accumulation of structurally abnormal glycogen in all tissues. It is due to various degrees of enzymatic defect at the level of the debranching enzyme (or enzymes). The debranching enzymes control the hydrolysis of glucose moieties at the branch points of glycogen where they are joined in a 1:6 linkage. When these enzymes are deficient, hydrolysis of the glycogen molecule at the level of the 1:4 linkages is possible. Partial hydrolysis of glycogen and intact mechanisms of gluconeogenesis explain why hypoglycemia is usually mild and occurs only under conditions of prolonged food deprivation. Type IV glycogen storage disease, due to a defect in the branching enzyme that leads to accumulation of an abnormal glycogen (starch-like amylopectin), causes liver cirrhosis and premature death; there is no hypoglycemia. Type V glycogen storage disease, or MacArdle's disease, is due to an absence of muscle phosphorylase that leads to the occurrence of muscular cramping upon exertion; here again, there is no hypoglycemia. Type VI glycogen storage disease, or Hers' disease, is an autosomal recessive disorder due to low overall liver phosphorylase activity that leads to hepatomegaly; it has been reported to be associated with mild to moderate hypoglycemia that occurs with fasting in young infants. Type VII glycogen storage disease results from deficient muscle phosphofructokinase activity. The symptoms are similar to those of McArdle's disease; no hypoglycemia is recorded. Type VIII glycogen storage disease is a rare disorder in which incomplete activation of the adenylate cyclase system leads to low phosphorylase activity and accumulation of glycogen in the liver and the central nervous system. Type IX glycogen storage disease exists in two forms. In type IXa, an autosomal recessive disease, a partial defect in phosphorylase kinase leads to accumulation of glycogen in the liver and secondary hepatomegaly. In type IXb, the recessive trait is sex-linked, affecting only males; the phosphorylase kinase defect is relatively severe and leads to accumulation of liver glycogen; and fasting hypoglycemia is observed. Type X glycogen storage disease is an extremely rare condition in which excessive liver and muscle glycogen storage is due to deficient activity of the cyclic AMP-dependent protein kinase, with the result that all phosphorylase would be in the β (or inactive) form, and therefore glycogen would not be degraded.

Functional Hypoglycemias

Alimentary Hypoglycemia

Consumption of carbohydrates by individuals who have had a gastrectomy may lead to severe hypoglycemia within 1–2 hours after the meal. This disorder is occasionally seen in patients who have not had a gastrectomy, but who for various other reasons have rapid gastric emptying. Rapid gastric emptying is frequently

encountered in hyperthyroidism. It had been thought that the rapid dumping of carbohydrate into the upper small intestine and the consequent early hyperglycemia cause reactive hyperinsulinemia and alimentary hypoglycemia. It is now generally accepted that, in addition, several gut factors are released after glucose ingestion, and act in concert with glucose, or even prior to glucose, to stimulate insulin secretion. Among these factors, secretin, glucagon-like peptide 1 (GLP-1), and cholecystokinin may be involved, as is gastric inhibitory polypeptide (GIP).⁴² A recent study has suggested that *Helicobacter pylori*-induced gastritis may contribute to the occurrence of postprandial symptomatic hypoglycemia, since *H. pylori* eradication is associated with a reduction in number and severity of postprandial hypoglycemic attacks.⁴³

Spontaneous Reactive Hypoglycemia

This entity is poorly defined. The term is usually applied to a syndrome with the following features: (1) symptoms that resemble those seen in insulin-induced hypoglycemia (diaphoresis, tachycardia, tremulousness, and headache, among others), but these are often accompanied by other symptoms less typical of hypoglycemia, such as fatigue, drowsiness, feelings of incipient syncope, depersonalization, irritability, and lack of motivation; (2) symptoms that may be episodic, and are sometimes aggravated by carbohydrate-rich meals; and (3) plasma glucose concentrations that drop to 45 mg/dL (2.5 mmol/L) or less at one or more of the half-hourly samples taken in a 5- to 6-hour glucose tolerance test. Abnormal insulin secretory patterns have been reported in certain patients, presenting as reactive hypoglycemia associated with impaired glucose tolerance (delayed and sometimes excessive insulin response), obesity (excessive insulin response), or renal glycosuria (excessive insulin response in about half the cases). Excessive insulin response has also been observed in about 50% of patients with isolated reactive hypoglycemia.

This entity has become widespread, particularly in the United States, over the past 30 years, but is more rarely diagnosed elsewhere in the world. The American Diabetes Association and the Endocrine Society have issued a joint statement to the effect that this entity is probably overdiagnosed. Indeed, the very existence of this condition is now called into question following several studies that have demonstrated that 25–30% of apparently healthy individuals without any hypoglycemic symptoms may exhibit low plasma glucose values when given a glucose load. Furthermore, the similarity of the symptoms to those of hyperventilation, and indeed with other functional syndromes, emphasizes the need to reevaluate the very existence of so-called functional or reactive hypoglycemia. The question of cause and effect has not been settled. It would be reasonable at present to restrict the diagnosis of reactive hypoglycemia to individuals in whom hypoglycemic blood glucose levels are demonstrated in samples taken after the sort of meals that are said to induce their symptoms. As shown by Palardy and associates,⁴⁴ these samples should preferably be taken at the time of symptoms and not only after a glucose load, which, as noted above, often produces low blood glucose values in normal people. Abnormalities in counterregulatory hormones have not been conclusively demonstrated to be associated with idiopathic reactive hypoglycemia. Increased insulin sensitivity has been documented in a euglycemic hyperinsulinemic glucose clamp in 10 out of 16 patients investigated by Tamburrano and colleagues.⁴⁵ Furthermore, and as discussed by Lefebvre,⁴⁶ some patients have adrenergic responses after a meal or during OGTT without hypoglycemia. Such “adrenergic hormone postprandial syndrome”

probably results from an altered glycemic threshold (a higher glucose level) for generating an adrenergic response, which results in confusion.⁴⁷

A critical analysis of the reactive hypoglycemia syndrome can be found in the proceedings of an international symposium held in Rome in September 1986.^{48,49}

Alcohol-Promoted Reactive Hypoglycemia

O'Keefe and Marks⁵⁰ have demonstrated that alcohol given in moderate doses (50 g) increases the insulin response elicited by the ingestion of insulinotropic carbohydrates, like saccharose, but not of noninsulinotropic ones, like fructose. They emphasized that drinks that contain both alcohol and glucose or saccharose (beer, gin and tonic, rum and cola, whisky and ginger ale, among others) are more likely to provoke hypoglycemia on an empty stomach than those containing only alcohol and saccharin or alcohol and fructose. Flanagan and colleagues⁵¹ have confirmed that in otherwise healthy individuals, a combination of gin and regular tonic can induce reactive hypoglycemia. Furthermore, they have shown that acute ingestion of alcohol impairs the epinephrine response and markedly suppresses the release of growth hormone in response to a fall in blood glucose levels.

Posthyperalimentation Hypoglycemia

Hypoglycemia has been reported following discontinuation of total parenteral alimentation. It is considered to be secondary to residual effects of insulin from chronically stimulated islets of Langerhans.

Endocrine Deficiency States

Hypoglycemia Due to Glucocorticoid Deficiency Glucocorticoid deficiency may induce fasting hypoglycemia due to defective gluconeogenesis.⁵² This condition may be encountered in acute or chronic adrenal insufficiency (Addison's disease), in congenital adrenal hyperplasia, as a consequence of removal or destruction of the adrenals, in panhypopituitarism, in isolated ACTH deficiency, and other conditions. Spontaneous hypoglycemia in patients with glucocorticoid deficiency mainly occurs if other precipitating factors such as alcohol ingestion, pregnancy, or prolonged fasting are present. It is important to recall here the danger of insulin or sulfonylurea administration to any patient with adrenal insufficiency.

Hypoglycemia in Growth Hormone Deficiency Growth hormone deficiency leads to hypoglycemia during a prolonged fast. This situation is accompanied by a marked sensitivity to both exogenous and endogenous insulin. Growth hormone deficiency may be isolated or part of panhypopituitarism (removal or destruction of the hypophysis). As reviewed by Gerich and Campbell,⁵³ the prevalence of fasting hypoglycemia is approximately 20% in children with hypopituitarism. Hypoglycemia occurs with equal frequency in children with isolated growth hormone deficiency and those with multiple pituitary defects. As noted previously, hypophysectomy results in increased insulin sensitivity, and therefore reduced insulin requirements.

Hypoglycemia and Catecholamine Deficiency For many years epinephrine deficiency has been considered as a possible cause of hypoglycemia in children. The so-called Zetterström syndrome is observed predominantly in male infants of low birthweight who do

not increase their urinary catecholamine excretion in response to insulin-induced hypoglycemia.

Hypoglycemia and Glucagon Deficiency Attempts to isolate a glucagon deficiency syndrome have been disappointing. Glucagon deficiency has been suspected, but not definitively proven, in some cases of neonatal hypoglycemia. In 1977, Vidnes and Øyasaeter⁵⁴ reported a patient with severe neonatal hypoglycemia with impairment of gluconeogenesis, in whom circulating glucagon levels were low (but not zero), and in whom treatment with glucagon resulted in a marked clinical improvement. Bleicher and colleagues⁵⁵ reported a case in whom arginine infusion induced hyperinsulinemia and hypoglycemia with unmeasurable plasma glucagon, an observation that supports the concept that the role of stimulation of glucagon by amino acids is to prevent hypoglycemia from the associated insulin release. The suggestion that glucagon deficiency may play a role in the pathogenesis of certain cases of reactive hypoglycemia seems to be ruled out.

Severe Liver Disease

Fasting hypoglycemia may result from severe liver damage caused by hepatitis (hepatitis fulminans), various poisons (carbon tetrachloride, chloroform, benzene derivatives, *Amanita phalloides* toxin, hypoglycins, and others), primary carcinoma of the liver, or thrombosis of the subhepatic veins (Budd-Chiari syndrome). Hypoglycemia results from insufficient liver glucose output.

Profound Malnutrition

Extreme malnutrition leads to hypoglycemia. It is also found with relative frequency in kwashiorkor. In infants, hypoglycemia may result from acute or chronic diarrhea.

Prolonged Exercise

In prolonged exercise, the glucose turnover is markedly increased because of simultaneously increased production and utilization. If exercise is too prolonged, too severe, and if nutrient intake and carbohydrate stores are insufficient, hypoglycemia can occur.

Autoimmune Insulin Syndrome

Since the description of the first case of autoimmune insulin syndrome in 1970, more than 200 patients with this syndrome have been reported, mainly in Japan.⁵⁶ The main clinical feature of the syndrome is the presence of hypoglycemic attacks associated with the presence of spontaneous antibodies against insulin (see review in Redmon and Nuttall⁵⁷). The mechanism whereby spontaneous antibodies against insulin are generated remains obscure. At least one-third of the patients with the syndrome have been treated with some drug containing a sulfhydryl group, like methimazole or penicillamine. These patients usually have huge amounts of extractable insulin in their plasma. The affinity constant of the antibodies of patients with the autoimmune insulin syndrome, as tested in Scatchard plots, is usually much smaller than that of insulin-treated diabetes. Hypoglycemia is considered to be the consequence of inappropriate release of insulin from the insulin-antibody complexes.

Antibodies Against the Insulin Receptor

Autoantibodies against the insulin receptor are usually observed in patients with type B extreme insulin resistance associated with acanthosis nigricans. As reviewed recently,⁵⁷ in some of

these patients the hyperglycemia remitted and the patients developed fasting hypoglycemia. Furthermore, some patients have been reported in whom fasting hypoglycemia was the initial presenting sign, suggesting the presence of autoantibodies against the insulin receptor. The hypoglycemia is attributed to an insulinomimetic action of the antibody. The reasons that some patients develop insulin resistance and hyperglycemia and others develop hypoglycemia are not yet clear. Remissions can be obtained by plasmapheresis, immunosuppression with alkylating agents, or glucocorticoid therapy.

Functional or Transient Hypoglycemia in Infancy

An encyclopedic review of hypoglycemia at birth and in infancy has been presented by Lteif and Schwenk.⁴¹ Many of the causes of infant hypoglycemia have already been mentioned. Other causes of neonatal or infant hypoglycemia will be briefly considered next.

Transient Neonatal Hypoglycemia Transient neonatal hypoglycemia is common⁵⁸; it can be observed in about 10% of live births, will be symptomatic in 30% of these cases, and occurs only during the first 3 days of life. It may be due to insufficient supply (delayed feeding), insufficient hepatic glycogen stores (prematurity, intrauterine malnutrition, dysmaturity, and perinatal stress), anaerobic energy production (secondary to hypoxia), or increased heat production (secondary to hypothermia).

Infants of Diabetic Mothers Infants of diabetic mothers frequently develop severe hypoglycemia during their first hours of life. It results from hyperinsulinemia caused by the β -cell hyperplasia, itself induced by fetal hyperglycemia of maternal origin. Relative hypoglucagonemia may be a contributing factor.

Erythroblastosis Fetalis Hypoglycemia is frequently associated with erythroblastosis fetalis, a consequence of rhesus immunization. As in the infants of diabetic mothers, hypoglycemia results from hyperinsulinemia caused by hyperplasia of the islets of Langerhans.

Leucine-Induced Hypoglycemia Certain infants develop hypoglycemia when given leucine or leucine-containing food. It should be emphasized that cow's milk is richer in leucine than mother's milk. Excessive insulin response to leucine is characteristic of the syndrome, and relative basal hyperinsulinism is also found when fasting hypoglycemia is present. Hypertrophy and hyperplasia of the islets of Langerhans are frequently found. In most cases, the onset of symptoms takes place prior to 6 months of age. Severe hypoglycemic attacks may occur postprandially or after short periods of fasting. Severe mental retardation occurs if diagnosis is delayed.

Ketotic or Ketogenic Hypoglycemia This form of childhood hypoglycemia is classically considered to be one of the most common forms of hypoglycemia of childhood. It is characterized by sporadic attacks of hypoglycemia and ketosis that occur preferentially after food deprivation between the ages of 1 and 8 years, usually with spontaneous recovery before 10 years of age. Hypoglycemia is consistently evoked within 24 hours by a hypocaloric ketogenic diet, but normal children exposed to the same diet may

show glucose levels equally as low as those of patients with ketotic hypoglycemia. As reviewed recently,⁴¹ more data accumulate indicating that ketotic hypoglycemia is not a specific entity, but may represent a metabolic derangement in the presence of various biochemical abnormalities; one of the main derangements leading to hypoglycemia and ketosis seems to be any disturbance of the gluconeogenic mechanisms, due either to an enzymatic block or due to a diminished availability of substrate. In addition to the idiopathic form, ketotic or ketogenic hypoglycemia has been reported in fructose-1,6-diphosphatase deficiency, hypoglycemia, growth hormone deficiency, adrenal medullary hyporesponsiveness, adrenal cortical insufficiency, branched-chain aminoacidemia, glucose-6-phosphatase deficiency, and amylo-1,6-glucosidase deficiency.

Maple Syrup Urine Disease Hypoglycemia is frequently encountered in patients with maple syrup urine disease. Its mechanism is still obscure. It usually clears with appropriate dietary treatment.

Adrenal Hyporesponsiveness Hypoglycemia with adrenal hyporesponsiveness is a distinct clinical entity found most frequently in children born small for dates after a complicated pregnancy. The hypoglycemic attacks, occurring between 0.5 and 5 years of age, are sporadic and occur without pallor or perspiration. The insufficient rise in urinary epinephrine during hypoglycemia often associated with insufficient cortisol rise has been interpreted as evidence for a dysfunction of the hypothalamic hypoglycemia center.

INVESTIGATION OF A PATIENT WITH POSSIBLE HYPOGLYCEMIA

Hypoglycemia should be suspected in all patients exhibiting the following signs and symptoms:

1. Presenting with the symptoms already noted
2. With seizures or episodic psychiatric syndromes
3. With coma of unknown origin
4. Presenting with stereotyped symptom patterns relative to similar or identical circumstances, such as in the fasting state, after muscular exercise, or a few hours after a meal
5. Any patient at risk of developing hypoglycemia (diabetic patients treated with insulin or sulfonylureas, alcoholics, and others).

However, before a detailed investigation is carried out, hypoglycemia must always be confirmed by an accurate measurement of the blood glucose concentration.

History

A complete history is essential in patients with possible hypoglycemic disorders. Relief of symptoms after ingesting food or sugar suggests the general diagnosis, whereas the relation of the symptoms to other events suggests the etiology. If the symptoms occur after a meal, the hypoglycemia is probably alimentary or reactive, whereas signs occurring in the fasting state or after exercise suggest organic hypoglycemia.

In diabetics receiving insulin, particular attention should be paid to the true dose of insulin injected, the site of injection (it has been claimed that insulin is more rapidly absorbed from an exercising limb than a resting site), the nature and quantity of food ingested, the importance of physical activity prior to the hypoglycemic episode, and the ingestion of alcohol or of various drugs. In diabetic patients on oral medications, the nature of the drug used should be documented, and the number of tablets ingested should be assessed. One of the major aims of the anamnesis should be to detect any drug that may have been simultaneously ingested and may have potentiated the hypoglycemic properties of the oral antidiabetic agents. Here also, alcohol should not be forgotten.

In a patient suspected of an insulinoma, the history frequently reveals that hypoglycemic symptoms are precipitated by fasting or exercise and relieved by food or sugar ingestion. This situation is also encountered in patients with extrapancreatic tumor hypoglycemia. In these patients, however, the discovery of the tumor often precedes the symptoms of hypoglycemia, but the reverse has been reported. Symptoms occurring early after food ingestion suggest alimentary hypoglycemia, while symptoms occurring 90 minutes to 5 hours after the meal suggest reactive hypoglycemia. The nature of the drink mixtures and cocktails consumed will permit diagnosis of alcohol-promoted reactive hypoglycemia. The interrogation of parents of infants presenting with hypoglycemia may lead to the diagnosis. For instance, symptoms occurring after ingestion of milk suggest leucine-induced hypoglycemia or galactose intolerance, whereas the abrupt occurrence of vomiting and hypoglycemia when a child who is breastfed is given his first drink of orange juice or is changed over to a diet containing fructose strongly suggests fructose intolerance. By definition, the history is often misleading in factitious hypoglycemia.

In a patient suspected of an autoimmune insulin syndrome, previous intake of drugs containing sulfhydryl groups (methimazole, penicillamine, and related compounds) should be carefully probed.

Physical Examination

As seen previously, when hypoglycemia is present, the symptoms result from both neuroglycopenia and the counterregulatory adrenergic reaction. In case of doubt, the prompt cessation of symptoms upon ingestion or injection of glucose is an easy means to confirm the diagnosis. It is important to recall here the fundamental rule that a blood sample must always be drawn to authenticate the hypoglycemia before glucose is administered. Between crises, the physical examination may be completely normal.

One should pay special attention to the following signs:

- A weight gain may occur in certain patients if hypoglycemic episodes are frequent; this has been reported in both organic (e.g., insulinoma) and functional (e.g., alimentary or reactive) hypoglycemia.
- A weight loss can be seen in nonpancreatic tumor hypoglycemia as well as in hypoglycemia associated with pituitary or adrenal insufficiency.
- Injection sites should be sought in factitious, suicidal, or criminal hypoglycemia.
- Acanthosis nigricans may be present in patients presenting with hypoglycemia due to antibodies against the insulin receptor with insulinomimetic properties.

- Hepatomegaly is usually present in the Nadler-Wolfer-Elliott syndrome and in various hypoglycemias of childhood (e.g., galactosemia and types I, VI, IX, and X glycogenosis).
- Abdominal and thoracic masses should be sought in tumor-associated hypoglycemia.
- Psychoneurotic symptoms are frequently associated with reactive hypoglycemia.

Laboratory and Technical Investigations in Endogenous Hypoglycemia

In this section, we briefly survey the main laboratory and technical investigations available at present to diagnose the most frequently encountered causes of endogenous hypoglycemia.

How to Explore a Patient Suspected of Presenting with an Insulinoma

An insulinoma should be suspected in any patient presenting with the triad described by Whipple: symptoms precipitated by fasting or exercise, hypoglycemia associated with symptoms, and relief of symptoms by glucose. However, as emphasized in all reviews on the subject, the demonstration of endogenous plasma insulin levels inappropriate to the prevailing blood glucose levels is the cornerstone of the diagnosis. Simultaneous determination of blood glucose and plasma insulin after an overnight fast or during a 24- to 48-hour fast is one of the best procedures to demonstrate relative hyperinsulinism. Various insulin suppression or stimulation tests are also helpful. Finally, when one is convinced of the diagnosis of insulinoma, every effort should be made to attempt to localize the tumor before sending the patient to surgery.

Basal Plasma Levels of Glucose and Insulin

Relative basal hyperinsulinism can often be demonstrated by the repeated (5–12 times), simultaneous determination of blood glucose and plasma insulin after an overnight fast. In normal individuals, fasting plasma glucose concentration is usually 70–110 mg/dL (3.9–6.1 mmol/L), with plasma insulin concentrations usually ranging between 5 and 15 μ U/mL. In obese individuals, basal plasma insulin is usually increased due to insulin resistance, and values up to 40–50 μ U/mL have been reported.

Circulating Levels of Glucose, Insulin, and C Peptide During a Prolonged Fast

A 24- to 48-hour fast in normal individuals is accompanied by a modest decline in blood glucose and a significant decline in plasma insulin and C peptide. The decrease in plasma insulin is usually 30–40%, relative to the values measured after an overnight fast. In patients with insulinoma, blood glucose declines markedly during fasting, while insulin and C-peptide plasma levels remain stable or decline only very moderately; relative hyperinsulinism therefore appears. If fasting has to be interrupted due to the occurrence of clinical hypoglycemia, a sample for blood glucose and plasma insulin determinations should always be taken before interrupting the fast or injecting glucose. According to Service and colleagues, a C-peptide plasma level above 0.2 nmol/L at the end of a prolonged fast is highly suggestive of the presence of an insulinoma.⁵⁹ In most patients with an insulinoma, symptomatic hypoglycemia will occur within a few hours of food deprivation.⁶⁰ In some, however, continuation of the fast for up to 72 hours may be necessary.⁶¹ Continuous nocturnal blood glucose monitoring has

been used to gather evidence of episodes of nocturnal hypoglycemia in insulinoma patients.

Insulin Suppression Tests

Suppression of endogenous insulin secretion by hypoglycemia induced by exogenous insulin administration is an elegant means to differentiate between insulin secretion under physiologic control and uncontrolled insulin release by tumoral tissue. In normal subjects, insulin-induced hypoglycemia induces a more than 50% reduction of plasma C-peptide circulating levels, indicating inhibition of endogenous insulin secretion by hypoglycemia (and maybe partly by insulin itself). Such inhibition is not observed in 90% of the insulinoma cases. The diazoxide infusion (600 mg over 1 hour in 500 mL saline) or oral (600 mg) administration tests can be confirmatory in showing a suppression of insulin and a correction of fasting hypoglycemia. These tests may be useful in foreseeing the effectiveness of chronic diazoxide therapy when surgical removal of the tumor cannot be realized. The response of basal and glucose- or glucagon-stimulated insulin release to an intravenous infusion of somatostatin is heterogeneous in the small series of patients studied with benign or malignant insulinoma. This test seems of little value in the diagnosis of insulinoma.

Other Determinations

In normal subjects, plasma proinsulin represents only 10–15% of the total immunoreactive insulin. In 85% of patients with insulinoma, the proinsulin component has been found to be elevated and exceeded 25% of total fasting insulin immunoreactivity. Values up to 80% have been reported in malignant insulinomas. Plasma levels of glucagon and pancreatic polypeptide may be elevated in insulinoma. Low levels of HbA_{1c} have been reported in 25% of the patients with insulinoma.

Localization of the Tumor

Diagnosis of an insulinoma on radiologic evidence is often difficult due to the usually small size of the tumor (see review in Grant⁶²). Selective arteriography via the celiac axis and the superior mesenteric artery localizes the tumor(s) in approximately 50% of the cases, but occasionally false localizations have been suggested by the arteriography. Tomodensitometry and ultrasonography help in the diagnosis of relatively large tumors whose diameter exceeds 2–3 cm. Magnetic resonance imaging using a high gradient power 0.5-T magnet has recently been shown most useful in the preoperative localization of insulinomas.⁶³ Percutaneous transhepatic catheterization of the splenic and portal veins can be used for selective retrograde venous angiography and for selective blood sampling and subsequent insulin plasma measurements: Higher plasma insulin levels are found in the vein or veins draining the tumor. One should always remember that in about 10% of cases there is more than one insulin-secreting tumor. External scanning of the liver following intravenous administration of technetium sulfur colloid or radiolabeled octreotide⁶⁴ can detect hepatic metastasis of malignant insulinomas. Günther and associates⁶⁵ have reported their experience in the pre- and perioperative localization of small (<2-cm diameter) islet cell tumors. Of 31 small tumors, 27 were correctly localized using a combined diagnostic approach: ultrasound was successful in 12 of 20 tumors, tomodesitometry in 9 of 21, angiography in 20 of 31, intra-arterial digital subtraction angiography in 1 of 2, and pancreatic venous sampling in 13 of 16. The smallest tumor found by ultrasound was 7 mm in diameter. Intraoperative ultrasound demonstrated all nine insulinomas exam-

ined. Rösch and associates⁶⁶ have shown that endoscopic ultrasonography is a highly sensitive and specific procedure for the localization of pancreatic endocrine tumors. Using this procedure, they were able to localize 32 of 39 tumors (sensitivity 82%), and no tumor was incorrectly localized. Among 22 patients who underwent both angiography and endoscopic ultrasonography, ultrasonography was significantly more sensitive than angiography for tumor localization (sensitivity 82% versus 27%). Among 19 control patients without pancreatic exocrine tumors, endoscopic ultrasonography was negative in 18 (specificity 95%). Proye and colleagues⁶⁷ have recently reported the potential of combining endoscopic ultrasonography and somatostatin receptor scintigraphy. Glucose-controlled insulin and glucose infusions (by an artificial pancreas) during surgical manipulation of the gland may help in localizing the tumor⁶⁸ as will the intra-arterial infusion of calcium.^{69,70} Like others,⁷¹ we have observed that intraoperative ultra-sensitive pancreas echotomography is also a most valuable procedure for localizing the tumor(s).⁷² In view of the performance of the combination of surgical operation and intraoperative ultrasonography, several groups now consider that preoperative localization of insulinomas is not necessary.^{73,74}

How to Investigate a Patient Suspected of Presenting with Non-Islet Cell Tumor Hypoglycemia

Basal and Fasting Levels of Glucose and Insulin

As in patients with insulinoma, patients with non-islet cell large tumor hypoglycemic syndrome usually have low fasting blood glucose, and in a starvation test, blood glucose continuously falls. In contrast to patients with insulinoma, insulin plasma levels are low and decrease to almost zero during fasting.

Dynamic Tests

Insulin suppression and stimulation tests are of little help. Insulin is usually markedly suppressed by the prevailing hypoglycemia. In provocative tests (with tolbutamide, glucagon, or leucine), the insulin response is usually low. In the OGTT, abnormal glucose tolerance with low insulin response is frequently found. The glycemic response to glucagon is usually normal, indicating the persistence of significant amounts of glycogen stores.

Other Determinations

As stated previously, hypoglycemia results from increased circulating levels of insulin-like growth factors, recently identified to be a large form of insulin-like growth factor II (big IGF-II).

Localization of the Tumor

Most of these tumors are large or very large and easy to localize on the basis of careful clinical examination, routine x-ray investigation (chest or abdominal roentgenogram), magnetic resonance imaging (MRI), or ultrasonography.

How to Investigate a Patient Suspected of Alimentary or Reactive Hypoglycemia

As stated earlier, there is little doubt that it would be ideal to restrict the diagnosis of alimentary or reactive hypoglycemia to individuals in whom hypoglycemic blood glucose levels (below 45 mg/dL or 2.5 mmol/L) can be demonstrated in blood samples taken in everyday life,⁴⁴⁻⁴⁶ preferably with the use of a memory glucometer,⁴⁶ or after the sort of meals that are said to induce the

symptoms. For practical reasons, however, this is rarely the case, and the oral glucose tolerance test (OGTT) is still widely (if not wildly) used as a routine tool for the diagnosis of the various sorts of postprandial hypoglycemia.

The Oral Glucose Tolerance Test

In the standard OGTT, using 100 g glucose, or as more recently recommended by various authorities, 75 g glucose, one or more blood glucose values below 45 mg/dL are found in these patients. The glucose nadir may occur early, at 90 or 120 minutes, and when this occurs it is usually preceded by an excessive early rise in alimentary hyperglycemia. In reactive hypoglycemia, the glucose nadir is usually found 3, 4, or even 5 hours after the ingestion of glucose. As already mentioned, excessive insulin response due to the rapid dumping of glucose into the upper small intestine is likely to be the cause of alimentary hypoglycemia. In reactive hypoglycemia, delayed and sometimes excessive insulin response is observed when the glucose tolerance is reduced; excessive insulin response is found associated with obesity or with half the cases of renal glycosuria. Excessive insulin response has also been observed in about 50% of patients with isolated reactive hypoglycemia. In 50% of patients with renal glycosuria and in 50% of patients with the syndrome, the insulin response is normal in time and magnitude.⁷⁵ In the late phase of the OGTT, an unequivocal rise in cortisol, glucagon, and growth hormone occurs following the glucose nadir.

Investigation of Gastric Emptying

Rapid gastric emptying, the causative factor in alimentary hypoglycemia, can be demonstrated by x-ray or isotopic studies of the upper gastrointestinal tract.

How To Deal with a Patient Suspected of Factitious Hypoglycemia

Surreptitious self-administration of insulin or sulfonylureas is not easy to detect²⁴ and can lead to a false diagnosis of islet cell disease.

C Peptide Measurements

The association of low blood glucose, high plasma insulin, and low C-peptide levels strongly suggests exogenous administration of insulin,⁷⁶ in contrast with endogenous insulin overproduction, in which low blood glucose and high plasma insulin levels are accompanied by normal or high C-peptide levels.

Detection of Factitious Hypoglycemia Due to Sulfonylurea Ingestion

Clandestine ingestion of sulfonylurea compounds may mimic an insulinoma both clinically and biologically. Screening plasma and urine for sulfonylurea compounds may establish the diagnosis.

How To Recognize Hormone Deficiency as a Cause of Hypoglycemia

Routine endocrinologic investigations will easily confirm a suspected diagnosis of glucocorticoid or growth hormone (GH) deficiency, panhypopituitarism, and catecholamine deficiency. Apparently extremely rare, the syndrome of glucagon deficiency could be diagnosed on the basis of a lack of glucagon rise during the insulin tolerance test, as well as in response to an alanine or arginine intravenous infusion. The insulin tolerance test is the most

commonly used procedure for revealing a state of increased insulin sensitivity, as well as for measuring the responses of the various counterregulatory hormones. The test is performed after an overnight fast, and the amount of soluble insulin given corresponds to 0.1 U/kg body weight in adults and 4 U/m² in children. Plasma samples are taken at 20, 30, 45, 60, 90, and 120 minutes after injection for measurements of ACTH, cortisol, and 18-OH desoxycorticosterone, adrenaline and noradrenaline, and growth hormone and glucagon. Urinary catecholamine excretion during the 3 hours following insulin administration gives an overall picture of the sympathoadrenomedullary responsiveness, mainly in young children. In adults suspected of presenting with GH or glucocorticoid deficiency, a first test can be performed using 0.05 U/kg body weight of insulin to avoid severe hypoglycemia.

How To Investigate Neonatal and Childhood Hypoglycemia

Neonatal hypoglycemia is often transient and will disappear spontaneously within the first 3–4 days of life. Priority should be given to careful monitoring of both infants who are known to be at risk (in a manner similar to that used for infants of diabetic mothers or those suffering from erythroblastosis) and infants who manifest clinical signs that could be due to hypoglycemia. Continuous monitoring, and if necessary intravenous glucose infusion, should be performed prior to any diagnostic investigation. If hypoglycemia persists after 3–4 days, organic hyperinsulinism or hereditary defects of carbohydrate or amino acid metabolism should be suspected.⁴¹

In neonatal hyperinsulinism, as in the insulinoma syndrome of the adult, the clue to diagnosis is the demonstration of excessive circulating insulin levels (in the peripheral or the portal blood) in the face of baseline blood glucose. In 22 neonates with focal hyperinsulinism, fasting plasma glucose averaged 1 ± 0.2 mmol/L and plasma insulin 20 ± 11 μ U/mL; 30 neonates with diffuse hyperinsulinism exhibited similar biochemical features: plasma glucose 1 ± 0.2 mmol/L and plasma insulin 22 ± 19 μ U/mL.³¹ In these infants, the insulin response to intravenous glucose is usually relatively small, suggesting that the β cells are already secreting maximally in the basal state; the glucose rise after glucagon injection is usually present, indicating the ability of glucagon to mobilize the glycogen stores.

In glycogen storage diseases, the most useful test is the glucagon test, in which 0.03 mg/kg of glucagon is injected intravenously. A normal blood glucose response is observed in types II, IV, V, VII, VIII, IXa, and X; in type I (von Gierke's disease), the injection of glucagon does not induce any rise in blood glucose, but does induce a rise in lactate; in type III, the response to glucagon is normal after food, but poor in the fasting state; in type VI, in which liver phosphorylase activity is absent, there is no glycemic response to glucagon; and in type IXb the response is poor. In all these cases, the diagnosis can be established with certainty by detailed enzymatic measurements on tissue (liver, muscle) biopsy specimens. The same applies for rare disorders such as hereditary fructose intolerance, fructose-1,6-diphosphatase deficiency, galactosemia, and phosphoenolpyruvate carboxykinase deficiency.

In hereditary fructose intolerance, the intravenous infusion of fructose (0.25 g/kg) invariably induces marked hypoglycemia, contrasting with the modest rise in blood glucose usually seen in normal children; in these patients, the blood glucose response to glucagon is normal, providing the test is not performed immediately after giving fructose. In fructose-1,6-diphosphatase deficiency, fasting induces hypoglycemia with simultaneous hyperlactacidemia

and often ketosis, hyperuricemia, and hyperalaninemia. In galactosemia, a significant fall in blood glucose after oral galactose (1.25–1.75 g/kg body weight) is observed in about two-thirds of the galactosemic patients, but in view of the toxicity of this sugar in these patients, this test is not recommended. Impaired oxidation of [¹⁴C] galactose by the red cells of these patients can be demonstrated *in vitro*. For establishing the diagnosis of leucine-induced hypoglycemia, a drop of the blood glucose level below 50% of the fasting level during the first 45 minutes of an oral leucine test (0.15 g/kg body weight) is required; an excessive insulin response is usually observed. The response to tolbutamide is abnormal in more than 80% of these patients. The leucine and tolbutamide tests should not be performed if the initial blood glucose is already low. For the diagnosis of ketogenic hypoglycemia, a hypocaloric high-fat diet (ketogenic provocative test) is commonly used. Urine should be tested every 2 hours for ketones, and blood glucose (and if possible plasma alanine) determined every 3–4 hours. For the diagnosis of growth hormone or epinephrine deficiency in children, the lack of increase in plasma growth hormone or in urinary epinephrine during an insulin tolerance test (0.1 U/kg intravenously) is the best criterion. The test should not be performed if the fasting blood glucose is not above 50 mg/dL (about 2.8 mmol/L).

TREATMENT OF HYPOGLYCEMIA

Prevention of Hypoglycemia

In many circumstances, the prevention of hypoglycemia is possible. In insulin-treated patients with diabetes, appropriate education is of paramount importance; they should know how to adjust their insulin regimen according to their daily needs, their food intake, and their physical activity (see Chap. 29). In adolescents, the use of continuous subcutaneous insulin infusion has been advocated to lower the risk of severe hypoglycemia, improve metabolic control, and enhance coping.^{77,78} Knowledge by the physician of the pharmacologic interactions of many drugs with both insulin and oral antidiabetic agents will permit the necessary adjustments of the doses of hypoglycemic agents when interfering compounds are simultaneously prescribed. Alcohol-induced fasting hypoglycemia can be prevented by advising the patient to consume an adequate amount of carbohydrate within 6–36 hours of ingesting moderate or large amounts of alcohol. In susceptible subjects suffering from alcohol-provoked reactive hypoglycemia, the incidence and severity of symptoms are reduced by decreasing the amount of sucrose (or glucose) ingested and by replacing it with either saccharin or fructose. Finally, the administration of acetylsalicylic acid in children below the age of 2 years should be avoided, and the daily dose, if used, should not exceed 10–20 mg/kg body weight every 6 hours. One must be particularly cautious in dehydrated children. Prevention of neonatal hypoglycemia implies the prenatal identification of infants at risk, such as infants of diabetic mothers or those suffering from erythroblastosis, as well as those who are small for dates, preterm, or the smaller of twins. Prophylaxis consists of reducing nonessential caloric expenditure, effecting heat conservation by nursing the infant in the appropriate thermal environment, and ensuring adequate caloric intake through a regimen of early feeding. Adequate and specific dietary changes prevent hypoglycemic attacks in patients with fructose intolerance (removal of sucrose, fruit, and fruit juices), galactosemia (galactose-free diet), and leucine-induced hypoglycemia. In children prone to ketotic

hypoglycemia, attacks can be avoided by insisting on a nighttime carbohydrate-rich snack and consumption of frequent small-to-moderate amounts of carbohydrate-rich foods, particularly during periods of mild illness. Finally, frequent feeding (every 2–3 hours) prevents severe hypoglycemia in type I glycogen storage disease; portacaval transposition performed in a few cases gave promising results. Hypoglycemia following total parenteral nutrition is prevented by starting an IV infusion of 10% glucose at the time of discontinuation and gradually decreasing the IV glucose load over 12 hours.

Management of Acute Hypoglycemia

When the patient remains conscious, ingestion of some form of sugar by mouth (soft drinks containing saccharose, sugar cubes, glucose tablets, or solution equivalent to 5–20 g of carbohydrate) is usually followed by rapid relief of symptoms. In the unconscious patient, intravenous injection of glucose should be given, approximately 0.5 g/kg body weight in children. In diabetics with severe hypoglycemia, glucose doses in the range of 25–50 mL of 30–50% solution should be given. Intravenous glucose should be maintained as long as necessary (possibly days in hypoglycemia due to long-acting sulfonylureas) until persistent euglycemia or slight hyperglycemia is present. Intravenous, subcutaneous, or intramuscular glucagon (0.5–1.0 mg) can be used to treat severe hypoglycemic reactions of insulin-treated diabetic patients. The patient will often become conscious in 5–20 minutes; if not, a second dose may be given. Glucagon is not effective for much longer than 1–1.5 hours, and the patient should eat a snack or a meal of at least 20 g of carbohydrates as soon as he or she becomes conscious to prevent hypoglycemia from occurring again. Glucagon is less suitable for treating hypoglycemic attacks in sulfonylurea-treated patients because hypoglycemia in this circumstance is much more prolonged. The symptoms of hypoglycemia yield almost immediately to intravenous glucose unless hypoglycemia has been sufficiently prolonged to induce organic changes in the brain. If the patient remains unconscious after prolonged hypoglycemic coma despite blood glucose levels in the range of 200 mg/dL, the blood glucose should be maintained at that level by a glucose drip to which 100 mg hydrocortisone should be added every 4 hours for the first 12 hours to minimize cerebral edema. Sufficient insulin should be given to prevent ketosis. Finally, rapid recovery of consciousness has been described in cases refractory to glucose and hydrocortisone following slow intravenous infusion of 200 mL of a 20% solution of mannitol. The possible side effects of this treatment should be kept in mind.

Etiologic Management and Particular Cases

Insulinoma

Single benign adenomas are most common and their removal by pancreatic surgery is the first and obvious choice of treatment.^{62,79} Preoperative localization of the tumor is recommended. The risk of the operation is related to the location of the tumor, being minimal with enucleation of the adenoma or distal pancreatic resection, and increasing if subtotal pancreatectomy or particularly if pancreatoduodenectomy is performed. Laparoscopic excision has been reported. Medical management of a benign tumor is reserved for patients who do not accept surgery or in whom major contraindications for the operation exist. In those cases, the management will often include diet with frequent meals, diazoxide,

which directly inhibits the release of insulin by β cells and also has extrapancreatic hyperglycemic effects, and a thiazide diuretic. Diazoxide daily doses range from 150–600 mg. High doses induce sodium retention and edema, which are counteracted by thiazides. In some cases of insulinoma, the anticonvulsant diphenylhydantoin (300–600 mg/d) has been used successfully for controlling refractory hypoglycemia.

Neonatal Hyperinsulinism Due to Nesidioblastosis

The initial treatment consists of glucose (up to 15–25 mg/kg/min), hydrocortisone (10 mg/kg/d), and diazoxide (20 mg/kg/d), as well as intermittent glucagon injections (0.1 mg/kg IM). If the situation is unstable with this therapy, removal of 75%, and sometimes in a second operation, of 95–100%, of the pancreas may be necessary to prevent severe hypoglycemia and secondary mental retardation. De Lonlay-Debeney and associates³¹ have recently reported that among 52 neonates with hyperinsulinism, 22 had focal adenomatous islet cell hyperplasia that was successfully treated with partial pancreatectomy. These neonates had been identified through pancreatic catheterization and intraoperative histologic studies. Striking beneficial effects of long-acting protamine somatostatin treatment have also been reported.⁸⁰

Autoimmune Insulin Syndrome

The drugs accelerating the production of insulin antibodies include methimazole, thiopronin, glutathione, and penicillamine. Definitive withholding of those drugs is mandatory because immediate recurrence of the syndrome has been reported after readministration of the incriminated drug.

Anti-Insulin Receptor Antibodies

Prognosis is poor in patients presenting with fasting hypoglycemia due to antibodies against the insulin receptor having insulinomimetic properties. In some patients, high doses of prednisolone (120 mg/d) have improved the situation. Other therapeutic approaches include plasmapheresis or immunosuppression with alkylating agents.

Malignant Tumors

Streptozocin, in association with fluorouracil or doxorubicin,⁸¹ is the most effective antitumor agent for treating metastatic malignant insulinoma, possibly after surgical reduction of the tumor mass and/or removal of liver metastases.⁸² Streptozocin causes selective destruction of the pancreatic β cell. It is often capable of controlling hypoglycemia, and in about half of cases causes a measurable decrease in tumor size. Renal tubular toxicity resulting in proteinuria is the most significant side effect. The treatment schedule is most often 1–2 g/m² administered every week. Medical treatment often involves diazoxide and a thiazide diuretic, the doses required often being higher than in benign tumors. Other compounds capable of alleviating hypoglycemia include glucocorticoids, which increase gluconeogenesis and insulin resistance, and high doses of propranolol or chlorpromazine, which in a small number of patients reduce plasma insulin levels. Besides streptozocin, other tumoricidal drugs have been used in a small number of cases: chlorozotocin,⁸¹ L-asparaginase, 5-fluorouracil, tubercidin, doxorubicin, and mithramycin. A few studies have indicated that some patients with malignant insulinoma can be improved by the use of the somatostatin analogue octreotide at 3–4 daily doses of 50–100 μ g^{83,84} or by radiotherapy.⁸⁵

Alimentary and Reactive Hypoglycemia

Diet is the first treatment of alimentary and reactive hypoglycemia.⁸⁶ Simple sugars should be omitted and replaced by complex carbohydrates. Alcohol consumption should also be limited. If symptoms persist, small but frequent meals (usually 6) of a high-protein, low-carbohydrate diet should be tried. When dietary management is insufficient, dietary fiber or anticholinergic drugs (such as atropine or propantheline) or both can be used to retard gastric emptying and the carbohydrate absorption rate. This is often necessary in patients who have had gastric surgery. The dose of propantheline is 7.5 mg 30 minutes before meals. Biguanides (such as metformin) may help some patients. In our experience the treatment of choice is acarbose, an α -glucosidase inhibitor that delays carbohydrate digestion and intestinal glucose absorption. With a dose of 50–100 mg at the beginning of the meal, acarbose significantly reduces postprandial hypoglycemia.⁸⁷ Similar results have been reported with miglitol, another α -glucosidase inhibitor.⁸⁸

Leucine-Sensitive Hypoglycemia

The treatment of leucine-sensitive hypoglycemia consists of frequent feeding and a low-leucine diet. In some cases, it is necessary to prescribe diazoxide, at doses ranging between 5 and 10 mg/kg/d. Hirsutism may complicate long-term treatment with diazoxide.

Economic Aspects: Insurance, Employment And Licensing

Christopher D. Saudek

Shereen Arent

Diabetes mellitus imposes significant social and financial as well as medical burdens. In 1997, diabetes cost the United States an estimated \$98 billion.¹ Interestingly, only \$7.7 billion of this was for acute glycemic care. The vast majority of the cost of diabetes is related to specifically related chronic complications (\$11.8 billion), excess prevalence of general medical conditions (\$24.6 billion) and attributable indirect costs (totaling \$54.1 billion, including \$37.1 billion for disability and \$17 billion for premature death).

At an individual level, even the person who is well adjusted and free of significant diabetic complications is affected financially by the disease. He or she may be blocked from purchasing adequate health, disability, and life insurance at an affordable price, because diabetes imposes a potentially high cost of medical care and risk of premature death. There may be hardship caused by unfair exclusion from employment opportunities. Employers may even terminate a person or seriously restrict opportunities for advancement because of perceived disabilities attributed to diabetes.

This chapter will address the economic dilemmas encountered by people with diabetes, insurers, and employers. The underlying theme is that the interests of all three can be reconciled within the law, and that the health care practitioner should know enough to help in this reconciliation process.

THE HEALTH CARE SYSTEM IN TRANSITION

Universal, all-inclusive health care reform has hardly been mentioned since the early 1990s.² But there is no doubt that the financing as well as the organization of health care is undergoing fundamental change in the United States. The shift toward managed care may be receding, with early signs of re-emphasis on patients' rights and broadening coverage. But even without knowing how it will all turn out, it is clear that many pitfalls as well as opportunities exist for people with diabetes. It therefore behooves health care professionals to understand and deal effectively with the forces at work.

Driving Forces of Health Care Reform

Two major forces drive every discussion of health care reform: the spiraling cost of health care in the United States and its inconsistent quality. While some moderation in expenditure growth was enforced in the first few years of managed care, costs again appear to

be spinning out of control,³ most recently at a rate of about 6.5% per year, with further acceleration predicted.⁴ Some 28% of the Medicare budget goes to health care for people with diabetes. Furthermore, Americans continue to spend a far higher fraction of the gross domestic product on health than any other industrialized nation. Moreover, indices of quality are not encouraging. There have been few international comparisons of the quality of care,^{5,6} but it is clear that we have a long way to go as a nation before all people with diabetes receive quality care. It is understandable, therefore, that patients, employers, providers of care, and third-party payers all have an interest in the economic consequences of diabetes.

Organization of Health Care

One reason our costs are so high and our quality so variable may be that in fact there is no health care "system" in the United States; rather, there is an almost unbelievably complex patchwork of different systems. Physician providers may practice alone or in a group. The traditional model of a physician earning a living by billings is far less prevalent than it was decades ago. In fact, while practitioner earnings based on billing may still be the majority approach, a great many health care professionals are now salaried, whether working in full-time academic positions, as military or public health service employees, working for large companies, or in health maintenance organizations (HMOs), or any combination of these. The certified diabetes educator has become a widely accepted profession, existing in a wide variety of practice settings.

Delivery sites also vary tremendously. They may be single offices, hospitals, or clinics operated by profit or nonprofit corporations; they may be university clinics, or federal, state, or local government facilities. It would be nice to think that people with diabetes are rationally triaged along a sequence of practice settings, with the most stable patients receiving basic, primary care, and the most difficult-to-manage receiving the attention of specialists. But such rational use of manpower is not the rule.

Payment mechanisms, too, are diverse and often without sound rationale. Examples abound of nonsensical decisions about "medical necessity" or "clinically indicated care." Therefore, an understanding of the various reimbursement systems in place and under development is necessary if we are to operate effectively in this consummately pluralistic environment, and bring some rationality or reform to it.

Methods of Coverage

Fee for Service Payment

This time-honored system is the equivalent of piece work, and the incentives are roughly the same: the provider is paid by the number of visits, tests, and particularly, procedures. Knowingly or not, providers often orient their practice toward a high volume of remunerative procedures. Insurance premiums escalate as the pay-outs to providers increase, making these "indemnity" insurance plans less price competitive. The only way to control the outlays is to discourage volume and hold down reimbursement, particularly of hospital days and procedures. Insurers who reimburse providers on a fee-for-service basis, then, initiate utilization review, preauthorization, and other means of reducing the volume of payments.

Prepaid Capitated Payment

Under capitated payment plans, an organization (for-profit or not-for-profit) is paid up front premiums and contracted to provide, not just pay for, the total care for enrolled individuals. Having already collected the fee, the delivery system loses, rather than gains, from every service it provides. The incentives, then, are the exact opposite of those operating in a fee-for-service mode: capitated systems profit by enrolling healthy people. The "staff model" HMO, first popularized in the 1970s, is the prototype capitated payment system. Professionals are hired by the corporation to provide care, and the corporation profits to the extent that cost per patient remains under the capitated rate.

Hybrid Systems

Virtually every imaginable permutation exists of pure fee-for-service, indemnity insurance, and the staff model HMO. HMOs open their panel, for example, to negotiate with outside physicians, offering a high volume of patients in return for a reduced per-service fee. Indemnity plans develop lists of "preferred providers" who, again, agree to accept a reduced per-service fee in exchange for volume. Physicians may be added to or cut from these lists based on the cost of their practice style. A system popular in the mid-1990s was the "point of service" approach, which allows enrolled patients to go outside a closed list of approved doctors, but the patient pays more out-of-pocket or a co-pay to do so.

It may be oversimplified to think that professionals respond only to the basic (and base) economic incentives described above—that fee-for-service physicians provide unneeded services just to increase income, and prepaid systems withhold needed services to increase their profit. But it also seems naive to imagine that physicians and managed care systems are immune to financial incentives. There is little doubt, for example, that capitated systems try to enroll healthy, low-risk people (known as "lives" in the industry), and there is little doubt that fee-for-service providers deliver more services to people with insurance coverage.

Competition in Health Care Delivery

A prevalent notion, popular among legislators and deeply rooted in the American psyche, holds that competition among providers will contain cost. There are basic flaws in this notion as applied to health care, however. For example, if "consumer" is taken to mean "patient," then shopping for the best deal is among the least likely behaviors when someone is sick.

The consumer need not be the individual patient, however, and indeed negotiations now occur much more effectively between

providers and professionals who represent large consumers of health care, such as corporations, unions, or government. As providers, not only physicians, but hospitals, HMOs, and indemnity insurance plans are all in fierce competition with each other. Competition is now a fundamental part of the health care landscape.

Even sophisticated negotiators in the diverse arena of health care finance are often ignorant of the needs of individual people with chronic diseases like diabetes. How may coverage negotiators, faced with decisions on open heart surgery sites, PET scanning facilities, or neonatal intensive care units, think a great deal about glucose monitoring strips or the importance of routine foot care? Professionals who are aware of these issues must speak out, demanding coverage of needed services for their patients.

Navigating the System for People with Diabetes

Availability of Health Insurance

Given the competitive incentives noted above, people with diabetes can find themselves excluded from insurance coverage, provided with minimal care, or forced to pay out-of-pocket for a substantial part of their health care costs. To prepaid and capitated providers, people with diabetes are a predictably high expense; there is no incentive for HMOs to enroll them or to retain them once enrolled. Insurers who pay fee-for-service and are concerned about the cost of premiums, can also do better simply by excluding from coverage preexisting conditions like diabetes.

Health insurance for people with diabetes will be more available, and the costs of caring for diabetes will be more equitably distributed, if these disincentives are rectified. Assuring that capitated plans take their share of sick people would help, as would prohibition of noncoverage for preexisting conditions. But the best way out of the quagmire may be to change the incentives themselves, through a process called risk adjustment.

Risk Adjustment

The arcane process of risk adjustment gauges how sick a particular group is and pays the provider a capitated rate according to the risk of the population covered. A managed care organization enrolling predominantly Medicare patients over 65 would receive more, per enrollee, than would one enrolling a young, working population. Without risk adjustment, as described, there is no incentive to care for the sick since it is cheaper to care for the well. In theory, resources are distributed according to the amount of care required and provided. Risk adjustment may therefore be the ultimate mechanism that will allow a pluralistic delivery system to survive in the United States. It is very much in the interest of people with diabetes to assure adequate compensation for quality care to people with known chronic disease.

Quality of Care Issues

Particularly with the benefits of glycemic control now well-proven, significant quality issues are raised. What supplies are reimbursed? What counseling services are provided? When should an endocrinologist be involved? A podiatrist? Self-management training? The case can and must be made that good self-care yields long-term financial savings, but this case may not be enough, when providers look at annual balance sheets. Even "outcomes research" can be misleading if it does not factor in the long-term consequences of poor care.

Standards of care should be disseminated and enforced, with all payers made aware that quality care is the right of all people with diabetes. Evidence should be gathered and summarized for the various aspects of quality care. "Medical necessity" should cover all elements of care proven to have benefit, not just those needed to allow the person to survive another day or year.

OBTAINING HEALTH INSURANCE

Harris and associates have compared the health insurance status of adults with diabetes versus those without.⁷ They concluded that 8% of adults with diabetes were without any health insurance. This is the same figure estimated much earlier by Krall.⁸ Harris and associates went on to find that the percentage of the sample covered by insurance was nearly equal for those with diabetes and for those without. Because having diabetes increases the likelihood of high medical expenses, however, it is particularly risky not to have adequate coverage. There is also evidence that the uninsured population with diabetes is increasing. In California, the number of uninsured people with diabetes increased 50% between 1979 and 1986. Many of these uninsured people were neither poor nor unemployed. Thus, finding adequate, affordable health insurance remains a major problem for people with diabetes.

Health insurance is obtained either through the private sector or by qualifying for a government-funded plan. While qualification criteria for government programs are relatively specific, there is, as summarized above, an enormous array of private health insurance options available.

Options for Health Insurance Coverage

For people with diabetes it is most important to have some form of health care coverage, and a prospective employer's insurance options may legitimately become the driving force when a person with diabetes chooses a job. While in large employer and "entitlement" programs, a series of choices are often available ("cafeteria" style), small employers may offer little or no health care coverage, and temporary or part-time work may be the worst option. In general, people with diabetes are well advised to look for work with a large company or the government.

Public Entitlement Programs

The federal government is the single largest provider of health insurance, and federal entitlement programs are often the most reliable source of health insurance coverage. Indeed, over 57% of Americans with diabetes are covered by federal programs.⁷ In addition to Medicare and Medicaid, the Department of Veterans Affairs and the Indian Health Service also provide care for large numbers of people with diabetes.

Generally, eligibility for public sector coverage is established as an "entitlement"—a right to coverage under law—if the person meets certain defined characteristics. Legislatures and federal or state agencies define exactly who is entitled to coverage under a given program, and the extent of that coverage. Medicare eligibility, for instance, is established mainly on the basis of age, disability, or end-stage renal disease. Receipt of veterans' medical benefits depend upon the person having served on active military duty. Medicaid is meant mainly for low-income people.

There may be, as with Medicare, a significant monthly fee to the enrollee, and often copayment is required. There may also be enormous coverage gaps, exemplified by the longstanding failure

of Medicare to cover pharmaceuticals or long-term care, both of which are clearly major health care needs of the elderly. These gaps in coverage spawned the market for supplemental, or "Medigap" insurance. "Medigap" policies are sold with the specific purpose of covering items government plans leave uncovered. However, there are two pitfalls: the policies may be redundant, re-covering what is already covered, and the price may be excessive (a judgment made by comparison shopping or by an independent insurance expert).

Principles of Private "Indemnity" Health Insurance

The principles which govern privately obtained coverage are quite different from those of public programs. In theory, private health insurance provides a risk-sharing approach: the cost of illness in a few is spread among many subscribers. As long as they comply with state laws, private insurers are free to offer whatever coverage they choose, to whomever they choose, at whatever price they choose. This freedom may allow the private insurer to refuse coverage, offer it only at a high price, limit benefits, or select their covered population by more subtle means such as targeted marketing campaigns.

Group Coverage

Over 80% of private health insurance is sold on a group basis, because actuarial calculations are more accurate if based upon relatively large populations. As few as ten subscribers may qualify as a group. Usually, group policies are obtained through employment, although associations such as unions and fraternal or professional organizations often offer group insurance. Until the day when portability becomes the rule (i.e., when a person's policy is not tied to the employer, but can be transported from job to job), it is crucial for people with diabetes to seek employment where group health insurance is offered, or to be sure they have access to a group policy elsewhere. The best option for keeping coverage after leaving a given employer is called COBRA.

COBRA is an acronym for Consolidated Omnibus Budget Reconciliation Act, and it has provided important protections since its passage in 1986. COBRA permits a person and their dependents to continue in a previous employer's group health plan after that person retires, quits, is fired, or has work hours reduced. Continuation coverage also extends to surviving, divorced, or separated spouses, and dependent children. COBRA continuation coverage generally lasts 18–36 months. A person may be eligible if the employer has 20 or more employees, but the person must pay the full premium him- or herself.

Group insurance is priced either by "experience rating" or "community rating."

Experience rating refers to the adjustment of rates based upon the health claims experience of a given group. This practice can work to the disadvantage of people with diabetes, especially if a small employer is singled out for rate increases because of a single sick employee. There may be pressure on the person with diabetes to leave employment or be removed from the company policy. For this reason, "community rating" is far more desirable. It adjusts rates based on the wider community, spreading risk broadly rather than penalizing subscribers for legitimate health care claims.

Individual Coverage

Policies rated and issued on an individual basis to people with diabetes are contrary to insurance theory, since they amount to collecting high premiums and paying out predictably high expenses,

rather than sharing the risk of illness broadly. Individuals, who have limited economic clout or a chronic disease such as diabetes, are thus at a great disadvantage in the individual coverage insurance market. This is the primary reason why a person with diabetes is best served when he or she is part of a large group. The person with diabetes is unattractive to the insurer and to the subscriber, and it may be impossible for that person to obtain coverage at a reasonable cost.

Pooled Risk Plans

Some states provide pooled risk plans to cover otherwise uninsurable risks. People can usually only apply if they have been rejected for standard individual policies. Although the programs vary from state to state, the cost of coverage is commonly 150% of the standard individual rate, sometimes with a deductible as high as \$2000. This price is far preferable to going without adequate insurance or paying exorbitant individual rates. Physicians and their patients can contact their state insurance commissioner to find out what is offered in their state. For more information, go to the website of the National Association of Insurance Commissioners at <http://www.naic.org/regulator/>.

HIPA

A more recent protective law is the 1996 Health Insurance Portability and Accountability Act or HIPA, which is intended to make it easier for people with preexisting conditions to get or keep health insurance, or to change from one health plan to another. This law sets national standards for all health plans. It also requires the consumer to meet very specific conditions for continuing to acquire insurance. Since states can pass different reforms for the health plans they regulate (fully insured group health plans and individual health plans), protections may vary from state to state. While the statute has provided assurances that people—even those with diabetes and other chronic conditions—must be able to purchase insurance, it unfortunately did not offer any price protections. Thus premiums offered may be quite high. However, for the person with diabetes, high premiums are often preferable to no insurance.

For more information on HIPA and other insurance issues, go to Georgetown University: <http://www.healthinsuranceinfo.net/>.

Community Health Centers: Help for the Uninsured

Harris pointed out in 1994 that almost 600,000 people with diabetes did not have any insurance coverage at all⁷. While 93% of all adults with diabetes had some form of insurance, there was marked variability based on ethnicity with, for example, 34% of Mexican-Americans uncovered.⁹

The nation's community health center (CHC) system currently provides health care to some 12 million people. Of these, about 25% or 4 million have no insurance at all. The two most frequently diagnosed conditions among those using the CHCs are hypertension and diabetes. The number of people served by community health centers is expected to increase dramatically, and federal funding for CHCs is also increasing significantly. The majority of community health centers receive partial funding from the Health Resources and Services Agency (HRSA). HRSA and the Centers for Disease Control (CDC) have collaborated on a program to improve diabetes care among those CHCs that do receive HRSA funding, and this has resulted in dramatic improvements in the frequency and results of the HbA_{1c} test. As part of the social safety

net, CHCs are required by law to see anyone seeking medical assistance and cannot turn away the uninsured.

Specific Issues in Health Insurance Coverage

In addition to physician and hospitalization fees, a number of expenses are part of necessary diabetes care. Indeed, the per capita medical costs for the person with diabetes is \$10,071 versus just \$2669 for the person without diabetes.¹ Among the individual costs may be durable equipment such as blood glucose meters and insulin pumps, orthotic shoes, or even prostheses. Diabetes care of course also often requires insulin, syringes, testing strips, or oral hypoglycemic agents. Yet, incredibly, these basic elements of self-management may not be reimbursed, while more expensive and less easily justified expenses such as hospitalization for diabetic control are well reimbursed.

Comprehensive patient education and access to the supplies and equipment needed to manage the disease are all integral to good diabetes care. In 1997, Congress passed a bill mandating that Medicare pay for blood glucose monitors and strips as well as diabetes self-management training. Passage of the legislation resulted from years of advocacy on the part of the American Diabetes Association (ADA) and other associations interested in improved care for diabetes. In 1998, the Health Care Financing Administration (HCFA) established rules to implement the glucose meter and strip coverage portion of the legislation. In February of 2001 Medicare established final rules for diabetes education programs, and reimbursement is now available for all the quality diabetes education programs recognized by the ADA.

Medicare coverage policy does not assure coverage by other insurance mechanisms, although the federal program is traditionally seen as the leader in coverage policy. And while the Medicare changes for diabetes coverage were going into effect, states were also improving coverage for people with diabetes. At this writing, thanks in large part to the American Diabetes Association and its partners, 44 states and the District of Columbia have enacted laws requiring state-regulated insurance plans to include coverage for diabetes supplies, equipment, and education as part of the basic coverage offered to all purchasers (Table 59-1). As many as one-third of people with diabetes get their insurance coverage from state-regulated plans. More information about coverage in a particular state is available through employers human resources departments, or through the ADA at 1-800-DIABETES.

Conclusion: Advising a Patient on Health Insurance

The following points should be emphasized in discussing health insurance with patients with diabetes:

1. Adequate insurance coverage for people with diabetes is essential. The adequacy of coverage should often be a significant factor in job selection.
2. Government entitlement programs, group health insurance policies, or pooled risk plans are usually far more cost effective than purchasing an individual insurance policy.
3. Insurance policies should be evaluated for specific covered benefits the individual with diabetes may require: specialist care, meters, glucose test strips, insulin, etc.
4. Reimbursement for diabetes self-management training is becoming more readily available, and is an important addition to the financing of diabetes care.

*United States Centers for Disease Control and Prevention (diagnosed and undiagnosed).

Approximately 33% of Americans are covered by private health insurance plans regulated by state laws. The remainder either have plans not regulated by state law (e.g., Medicare, ERISA-exempt, Federal Employees Health Benefit Plan) or have no coverage at all.

LIFE INSURANCE

Diabetes, despite its variability in clinical outcome, does increase the risk of premature death. For this reason, life insurance may be difficult to obtain and relatively expensive. However, life insurance policies are available, even for the individual with type 1 diabetes. Two points are worth noting. First, the patient and the physician must be honest in recording significant, known diagnoses on any

application. Hiding a diagnosis of diabetes may invalidate a policy if payment becomes necessary, and may also leave the physician open to charges of providing (by omission) false information. Second, if the actual diagnosis is not in fact diabetes mellitus, but impaired glucose tolerance with borderline or high risk of developing diabetes, then the word "diabetes" should *not* appear, lest the person be saddled with the economic penalties of a disease he or she does not have.

EMPLOYMENT

Potential employers, employees, and society at large have fundamentally different employment priorities. Employers want to hire the person who will accomplish a job with optimal reliability, and minimal absenteeism, disability, or cost to the company. Employers may act with little understanding of, and less concern for, diabetes. The job applicant wants the job. Society wants to minimize accidents while practicing fair and nondiscriminatory employment practices.

Job discrimination law balances the needs of the employer with those of the employee and society. For example, the employer can legitimately take into account whether a person's disabilities or limitations will interfere with specific job performance. Poor vision due to diabetes may disqualify a person from a secretarial job just as surely as would poor typing skills. Peripheral vascular disease with claudication may disqualify a person from a job that requires extensive walking. But it is not permissible for an employer to assume that just because someone has diabetes, he or she has poor vision or claudication. Moreover, simply having these complications of diabetes does not disqualify a person for a job if, with reasonable accommodations, that person can perform the essential functions of the job.

Physicians are often asked to evaluate a person for employment, acting as the intermediary between the patient, the employer, and society. Whether paid by the individual patient or the employer, it is necessary to understand what constitutes employment discrimination, which areas are most problematic for people with diabetes, and what the physician should look for in performing a medical evaluation. The first issue, then, is whether the person is medically qualified for the job (i.e., whether the diabetes or its complications would keep him or her from doing the work safely and well).

Assessment of the ability to do the job is not always as straightforward as it seems, since there is a requirement that employers make a "reasonable accommodation." Checking blood glucose, access to a snack, or taking insulin would generally be considered reasonable accommodations, easily accomplished at almost any workplace. Other less obvious but applicable accommodations could include a large-print computer screen for a secretary with retinopathy, or permitting a cashier with neuropathy to sit while on the job. Whatever accommodation is required, it must be provided unless the employer can show that doing so would cause undue hardship.

Safety is often another contentious issue. An employer may require that the individual not pose a "direct threat" to his or herself or to others in the workplace. The risk of hypoglycemia is frequently cited, often with the most severe hypoglycemic reactions described. But under this standard, an employer is not permitted to deny employment opportunity because of a slightly increased risk, a speculative risk, or a judgment based on stereotypes about people with diabetes.

To summarize, in evaluating a person for a given job, that person must first be deemed medically able to perform the job safely, with reasonable accommodations by the employer. In such a case, federal law specifically prohibits discrimination.

Laws Prohibiting Discrimination on the Basis of Disability

The Americans with Disabilities Act of 1990 is the most comprehensive federal law prohibiting discrimination on the basis of disability. The goal of the Americans with Disabilities Act is to eliminate discrimination against persons with disabilities in employment, education, and recreation, and to require equal access to a broad range of facilities and services.

The act prohibits employment discrimination by state and local governments and by private employers that employ over 15 employees. The earlier Rehabilitation Act of 1973 had similar prohibitions against employment discrimination, but applied only to the federal government and employers that either receive federal funding or that contract with the federal government.

Both laws prohibit discrimination in hiring, firing, promotion, training, compensation, or any other term or condition of employment, and both laws generally use the same standards to determine what constitutes unlawful discrimination. The Americans with Disabilities Act, the federal law, prohibits discrimination against a "qualified individual with a disability."

However, it is far from clear exactly what is and what is not a "disability." Unless a person with diabetes meets the legal definition of having a disability, there is little under federal law to stop an employer from refusing to hire a person, or taking other adverse employment action against that person simply because he or she has diabetes.

Legally, the term "disability" is defined as follows:

1. A physical or mental impairment that substantially limits one or more of the major life activities of such an individual;
2. A record of having such an impairment; or
3. Being regarded as having such an impairment.

"Major life activities" could include eating, sleeping, working, learning, seeing, walking, and many others. To be "substantially" limited under the law means to be unable to perform the major life activity or to be significantly restricted in its performance *when compared to the average person*.

Recent Supreme Court decisions have made it more difficult for people with diabetes to establish that they are protected under antidiscrimination laws. In 1999, the Court ruled that a person must be viewed in his or her "mitigated" state, which means taking into account the positive and negative effects of any medications or aids the person uses. Thus, for a person with insulin-treated diabetes, the court must evaluate whether or not the person is disabled *when taking medications*; the need for insulin itself does not amount to a disability.

Dietary requirements may qualify a person with diabetes as being covered by the Americans with Disabilities Act. The intricacies of balancing food and insulin, for instance, may be considered a significant restriction when compared with people who do not have diabetes.

Three more important points: First, it is not acceptable for an employer to make a class decision (for example, that taking insulin does not qualify as a disability). Disability decisions must be the

result of an *individual* inquiry, based on up-to-date medical information. Second, the physician's report should not be the sole basis of a disability decision. Other important factors include the individual's employment history as well as medical history. Finally, it is not legal for an employer to base the disability decision on whether insurance rates will increase or on the fact that the employer does not want to provide reasonable accommodations.

In addition to the federal laws, each state has its own antidiscrimination laws. Some, like those in New York and California, provide broader coverage than the federal law, so that people with diabetes are unquestionably covered against employment discrimination on the basis of having diabetes.

Another federal law that is often useful to people with diabetes is the Family and Medical Leave Act (FMLA). This law permits most government workers and employees of private companies with over 50 employees to take up to a total of 12 weeks of unpaid medical leave each year to deal with their own, or an immediate family member's, serious health condition, without losing their job.

The Employment Policy of the American Diabetes Association

The American Diabetes Association has worked hard and effectively to reduce discrimination against people with diabetes. A position was adopted in 1990 (based on a policy formulated in 1984), and is consistent with the Americans with Disabilities Act. It provides that: "People with diabetes should be individually considered for employment based on the requirements of the specific job. Factors to be weighed include the individual's medical condition, treatment regime (medical nutrition therapy alone, oral agents, and/or insulin) and medical history Any person with diabetes, whether insulin-dependent or non-insulin-dependent, should be eligible for any employment for which he/she is otherwise qualified."

Thus, the American Diabetes Association's policy, consistent with federal law, opposes any blanket exclusion of an individual with diabetes from a particular job or line of work. The diagnosis of diabetes should not, *per se*, make a person ineligible for any job. This does not, of course, imply that every person with diabetes is qualified for every job, or that physical limitations imposed by diabetes cannot be a factor in determining someone's ability to perform a job. It simply states that each case must be considered on its own merits, on a case-by-case basis.

Employment Discrimination in Practice

Despite federal and state laws that should provide protection for people with diabetes, discrimination is still pervasive, and may begin with unlawful preemployment inquiries. "Do you have diabetes?" for example, is not a permissible interview question. By law, the employer is permitted to ask only those questions necessary to determine the applicant's eligibility to be considered for employment in a particular position.

An employer's ability to make disability-related inquiries or require medical examinations is analyzed in three stages: preoffer, postoffer, and during employment. Prior to an offer of employment, an employer cannot require a medical examination or make any disability-related inquiries. Once an applicant has been given a job offer conditional upon passing a physical examination, an employer may make disability-related inquiries and conduct medical

examinations, as long as all incoming employees are treated equally. After the person becomes employed, an employer may make disability-related inquiries and require medical examinations only if there is a job-related reason for doing so.

The Health Professional's Medical Evaluation of a Person for Employment

The health care professional is best thought of as working on behalf of the patient, the employer, and society, reconciling the needs and rights of each. The medical evaluation yields only a recommendation, without the force of law or the authority of a licensing agency. We know of no cases in which physicians have been held legally liable for the results of a recommendation to hire a person with diabetes, so the examining physician need not be excessively concerned about his or her own liability. Nor should the positive qualities be forgotten, since people with diabetes may as a group have many favorable employment characteristics that are well worth emphasizing. Disciplined behavior, reliability, a healthy diet, and a generally health-conscious lifestyle may translate into above-average work habits.

The possibility of complications occurring at some later time should not be used to keep someone out of a job. Complications progress at such variable rates that it is medically unsound to assume, for example, that background retinopathy will progress to visual impairment, or that mild neuropathy will become severe. Long-term complications are relevant only when, at the time in question, they interfere with performance of the job or safety on the job.

Clinical or laboratory evaluation of a patient's blood glucose control as assessed by a given blood glucose or hemoglobin HbA_{1c} level is not usually relevant to a job evaluation. An exception might be that extremely poor control can cause generalized fatigue or the need for frequent urination. But mild to moderate hyperglycemia is rarely a significant risk to job performance. The immediate risk posed by an insulin reaction is usually the primary issue.

Considering hypoglycemia specifically, adrenergic symptoms, or even profuse diaphoresis and tachycardia are also generally of little concern if these conditions are reliably self-treated before a threat is perceived. But when there is a relatively recent history of altered mentation requiring the assistance of another competent person, the risk of a threat increases.

Evaluation of the Job

Is a particular job suitable for a given person with diabetes? As noted, a job should be considered suitable unless the person cannot perform the job adequately or will create a direct threat to others.

In the particular job, would even brief periods of confusion or loss of reflexes have serious consequences? In jobs involving driving or operating heavy machinery, the person's likelihood of having a serious hypoglycemic episode must be carefully assessed. Given that the past is the most accurate predictor of the future, a history of confusion during hypoglycemic reactions may be the most important historical point. Various specific regulations (see section on driving, below) have been devised to try to codify the assessment of risk, and most require a minimum period of freedom from severe hypoglycemia.

Existing complications of diabetes must be considered. For example, microelectronics assembly work may require perfect vision, and night watch work may require good night vision. A high level

of physical activity may be unsuitable for a person with unstable coronary artery disease. Long-distance driving may not be advisable for a person with hypoglycemic unawareness.

Will a given job adversely affect the person's health? For instance, irregular shift work may be detrimental if a person has unstable diabetes and does not practice good self-care. In these cases, a physician may advise the patient about what is in their medical best interest, although if the person chooses to apply for a given job, they cannot be discriminated against solely on the basis of paternalistic concern for their own health.

Problem Areas in Employment

Historically, the rationale for discriminating against people with diabetes has usually been based on the chance that a severe hypoglycemic incident could create an immediate danger to other people. There has been across-the-board discrimination in jobs that require driving, flying, law enforcement, and all positions in the military. These blanket prohibitions, however, were created when there were fewer and less effective management tools, and severe hypoglycemia was a greater risk. Individuals must be carefully evaluated by licensing bodies, employers, and physicians asked to make an objective risk assessment.

Trucking

Regulations of the United States Department of Transportation (DOT) presently disqualify anyone with diabetes requiring insulin treatment from driving a commercial motor vehicle in interstate or foreign commerce. Thus, if a person needs insulin, he or she must either leave driving as a profession (or give up the chance to make it a profession), avoid taking insulin despite clinical need, or cover up the need for insulin. Despite this federal blanket ban, however, most states have waiver programs that, under various conditions, allow some people with insulin-treated diabetes to drive some commercial vehicles within the state.

In 1998, the DOT was ordered by Congress to consider allowing certain individuals with insulin-treated diabetes to operate commercial motor vehicles interstate. As of this writing, the details of any new policy are not clear, but it is possible that by following a strict set of guidelines designed to minimize the chance of a serious hypoglycemic episode, people treated with insulin may be able to obtain a commercial license to drive interstate.

Opening the door to interstate commercial driving is being accomplished by the concerted efforts of the American Diabetes Association and others. As with so many other "test cases," it can have reverberations well beyond the drivers themselves, since many government agencies and private companies look to DOT for guidance in this area.

Law Enforcement

Evaluation of the job and the person is especially important when considering law enforcement work. Physical demands and irregular meal schedules make these jobs difficult. Confusion caused by severe hypoglycemia could have serious consequences. But none of these factors are absolute contraindications for employment in law enforcement, and many people with diabetes have performed in an exemplary fashion as law enforcement officers.

Law enforcement agencies may be under local, county, state, or federal jurisdiction. While all are subject to federal antidiscrimination laws, both written regulations and actual practices vary widely from place to place. Some law enforcement agencies dis-

qualify all those taking insulin, some have no written policy but *de facto* exclusion of people with diabetes if the physician who clears recruits has a personal bias, and still others have a protocol to individually assess whether a given candidate with diabetes is qualified for the job.

Key federal law enforcement agencies used to automatically disqualify anyone with insulin-treated diabetes. As a result of a lawsuit against the Department of Treasury, it was forced to abandon its hiring policy of automatic disqualification and now considers hiring individuals with insulin-dependent diabetes on a case-by-case basis. Similarly, the Federal Bureau of Investigation U.S. Marshal's Service, the Bureau of Prisons, the Drug Enforcement Administration, and the Immigration and Naturalization Service have all been banned from discriminating on the basis of diabetes as such. Unfair individual cases of discrimination may still exist, but the changes in federal law enforcement policy are an important step in removing the unwarranted discrimination often faced by people with diabetes.

Military

The U.S. armed forces are a major employer, and diabetes still makes a person ineligible for employment in the military, regardless of insulin use or not, duration, or status of complications. In addition, a new diagnosis of diabetes may well cause termination of current employment in the U.S. military. By contrast, in Israel, even insulin use does not disqualify a person from active combat duty. Appeals can be made to medical boards in the various branches of the military, and in at least one test case pursued with the army, such an appeal was successful. In general, though, a pre-existing diagnosis of diabetes will keep a person out of the military, and new onset of diabetes during military service may be cause for discharge.

In evaluating military employees and applicants, physicians should bear in mind that the diagnosis of impaired glucose tolerance is not a diagnosis of diabetes¹¹, and should not disqualify a person from holding any job. Physicians should also be especially mindful of the fact that early termination can seriously affect a person's retirement benefits.

LICENSING ISSUES

License to Drive

Driver's licenses are issued by states, and except with regard to commercial drivers licenses, medical standards for licensure are established on a state-by-state basis. Laws and regulations may therefore vary widely. In every case, though, the physician's role is that of advisor to the state agency, not a guarantor that any given patient drives safely. The medical evaluation form in California, for example, states "The Department of Motor Vehicles is solely responsible for any decision regarding the patient's driving qualification and license." It is the health care professional's job, then, not to guarantee that a person is a safe driver, but to consider facts that may affect whether or not to recommend that a person should drive a motor vehicle.

The data are few and inconclusive regarding whether, overall, people with diabetes have more motor vehicle accidents than others. One study suggested that women with diabetes may have an increased accident rate,¹⁰ but controversy still exists. Clarke and colleagues^{12,13} suggested that people with diabetes often choose to

drive when their blood glucose is too low.¹⁹ Certainly in aggregate, the number of accidents caused by medical conditions are small compared to those caused by alcohol abuse or negligent driving.

State policies vary widely in their treatment of issuing driver's licenses to diabetics.²⁰ An absurd example is that until relatively recently, the criteria for determining whether a government employee who had diabetes could drive on the job in some Maryland counties was whether he or she took more than 25 units of insulin per day! Routinely, driver's license applicants are asked directly if they have diabetes. If so, a statement from a physician is required. If a person with diabetes is involved in an accident, a report is prepared that usually indicates that the driver has diabetes, and in some states, his or her license is suspended immediately pending a hearing, whether or not hypoglycemia caused the accident.

In considering whether to support a person's application for a driver's license, the same issues discussed above would apply: Does the applicant have severe long-term complications such as impaired vision, impaired night vision, severe peripheral neuropathy, or impairments from cerebrovascular accidents? Do they have a history of hypoglycemic unawareness coupled with prior incidents of severe hypoglycemia? Do they have good self-care practices, and a thorough understanding of, ability to anticipate, and the means to self-treat hypoglycemia?

In summary, no state automatically disqualifies people with diabetes from obtaining a noncommercial driver's license. States do rely heavily on the treating physician for a recommendation, but the physician is not the final arbiter, and a good medical evaluation is not a guarantee of safe driving. States generally have the authority to impose conditions or restrictions on the license issued, such as requiring the driver to submit a medical report on a regular basis.

Other Licenses

Beyond driver's licenses, there are a number of other licenses that are important to people, and these may be restricted by the diagnosis of diabetes. Intrastate commercial driving such as driving a school bus may be restricted by state laws. People with insulin-treated diabetes in the past were categorically denied a license to fly both commercial or noncommercial airplanes. However, in 1996, the Federal Aviation Administration (FAA) changed its policy to allow people with insulin-treated diabetes who want to fly private non-commercial airplanes to be able to do so. The FAA set up a protocol for the effective screening, monitoring, and managing of pilots with insulin-treated diabetes.

Health Education for Diabetes Self-Management

Elizabeth A. Walker

Judith Wylie-Rosett

Harry Shamoon

It has long been recognized that persons with diabetes have much to learn about self-care, as well as lifestyle changes to adopt and maintain, in the ongoing management of this chronic disease.¹⁻³ Traditional models of the educational process, however, do not adequately address *how* to teach persons with chronic disease, so that when making informed choices they can learn and sustain changes in behavior related to health over their lifespan.⁴ Learning for lifestyle change is a complex process that requires assessment, coordinated planning, and individualized implementation, with both process and outcome evaluations.⁵ This chapter addresses *health education* for self-management of diabetes as a more broad topic than either patient education or diabetes education.

We will provide an overview of teaching–learning principles for health education, including several behavioral models applicable to diabetes self-management. The phases of the education process for both individual patients and groups will be examined in the context of practice settings, followed by a description of the new revised content areas related to diabetes self-management education. Information about practical aspects of creating a diabetes education team, educational program structure, and resources for educational materials will assist health care professionals to provide access to health education for diabetes self-management for their patients.

APPLYING PRINCIPLES OF TEACHING AND LEARNING

Education: Teaching and Learning

These three concepts take on special meaning when applied to patients with diabetes, their families, and support systems. *Teaching* involves an interaction between two or more persons or systems; *learning* denotes a change in attitude, knowledge, or capability, persisting over time (i.e., a change in behavior). The word *education* generally describes the total process, encompassing the various modes of teaching and the many styles of learning.⁵⁻⁷ A basic and tremendously important educational principle is that *teaching does not necessarily lead to learning*. Additionally, knowledge is a necessary component, but knowledge is not sufficient for learning and behavior change. For example, a simple demonstration of the procedure to test blood glucose does not guarantee that patients will understand how to do it or why they should test their blood glucose, or that they will consistently perform this behavior. Edu-

cation is a process requiring assessment, planning, implementation, and evaluation for successful outcomes, especially when daily diabetes self-management and adoption of lifestyle changes are among the goals.

Cognitive, Affective, and Psychomotor Learning

Bloom⁸ and others described three major domains of learning: cognitive, affective, and psychomotor. Briefly stated, the cognitive is the domain of information or knowledge; the affective domain can be described as the domain of attitude and belief; and the psychomotor domain encompasses skill acquisition and performance. Acknowledging and discriminating among these three domains can remind health care professionals of the complexity of the teaching–learning process for a chronic disease like diabetes. In the following example the utility of considering domains of learning is highlighted.

A capable 23-year-old man, newly diagnosed with type 1 diabetes, must learn to administer insulin to maintain independence. Thus information about the need for insulin and the timing of injections, as well as the procedures for the drawing up and injection of insulin, are part of the cognitive domain. However, the person's attitudinal response (e.g., his fear, negativity, intention to follow medical advice) to the recommendation for self-injecting insulin is part of the affective domain. The psychomotor domain involves this person's physical ability, coordination, and skill in completing the process of insulin administration.

If the educational assessment and planning for this young man were based on any one of these three domains and not the others, the desired outcome would likely not be achieved or maintained over time. The interaction between patient and health professional in the health education process emerges as various elements of diabetes self-management skills are assessed.

Optimizing the Learner's Experience

Table 60–1 provides examples of characteristics of adult learners^{6,7,9,10} that may be helpful to clinicians and educators in planning health education. Using these principles in practice, for example, when there are several topics to be discussed, encourages patients

TABLE 60-1. Selected Characteristics of Adult Learners Applied to Diabetes Education

- Adults must have a “felt need to know” the information presented: Begin with a brief rationale for the content.
- Problem-oriented learning is more acceptable to adults: Frame the diabetes education as problems to be solved or challenges to be overcome in collaboration with their health professionals.
- Self-directed learning enhances the person’s sense of autonomy: Allow choices when feasible—in the mode of learning, time spent on specific topics, and the order of the information to be addressed.
- Incorporating the person’s life experiences will enhance adult motivation to learn: Allow time in educational interaction for patients to share their past experience or current knowledge of this diabetes care topic.
- Learning can be threatening to the learner: Assess for fear as a barrier to learning diabetes self-management skills.
- Active participation of the learner is essential for a change in behavior to take place: Speaking, reading, writing, demonstrating, or problem-solving activities should be incorporated into the educational plan.

to verbalize what they see as a learning priority. Recent literature on teaching and learning strongly emphasizes individualization of the process as imperative for learning and sustained behavior changes. In many cases the process cannot be rushed, and health professionals have the challenge of planning their time to incorporate these principles.

BEHAVIORAL MODELS RELEVANT TO SELF-MANAGEMENT EDUCATION

Because of the chronicity and complexity of therapeutic regimens for diabetes, models to help explain human behavior in coping with diabetes can be useful to clinicians in teaching both individuals and groups. Models are also used to plan programs or systems for delivery of diabetes care. The following selected behavioral models have been considered useful by health care professionals for designing learning experiences and enhancing adherence to diabetes regimens.

Self-Efficacy

Self-efficacy is a construct of Social Learning Theory, which posits that self-efficacy is predictive of outcome and that persons are more likely to perform behaviors if they feel confident that they are *able to perform* the particular behavior.¹¹ For example, exercise self-efficacy has been found to be predictive of weight loss.¹² In practice, instructing a middle-aged man with type 2 diabetes about increasing his exercise by walking 1 mile each day may be effective only if he is *confident* that he can walk that far and can actually adopt this change from his current lifestyle.

A practical application of the self-efficacy construct is for health professionals to ask patients, “Do you think you can do this?” “How confident are you that you can . . . ?” The query should be made specific for each health behavior under consideration. A broad, “Can you take care of your diabetes?” may not be helpful for diagnosing a behavioral challenge. If a patient replies, “Not at all,” “I probably can’t do it,” or “No way!,” then the planning and nego-

tiation process must continue until the stated goal is feasible and mutually acceptable, and the action phase can begin.^{13,14}

Stages of Change

A more recently developed model for the process of changing behavior is the Stages of Change (or Transtheoretical) Model.^{15,16} This model has been widely studied in persons with addictive behaviors such as smoking,¹⁷ and it has been found to be predictive of change for some self-care behaviors such as exercise, weight control, and mammography screening. The model describes five cyclical stages in readiness for behavior change. These stages include: precontemplation, contemplation, preparation, action, and maintenance.

After assessing for the particular stage, health professionals can develop and plan interventions relevant to the patient’s current stage of change.¹⁵ For example, if a person who smokes cigarettes has not even considered quitting smoking, it is probably premature to encourage them to enroll in an action-oriented smoking-cessation program. Rather than immediate action, providing information relevant to smoking cessation may be more beneficial at this stage. Specific application of these five stages of change to diabetes education and care¹⁸ is described in this chapter under the assessment phase of the health education process.

Autonomy and Patient Empowerment

A model incorporating the construct of autonomy would highlight issues related to an individual’s desire to be competent and self-determining related to his or her environment, including a chronic disease like diabetes. There is some evidence that patients with diabetes who have providers who support their autonomy may have improved outcomes.¹⁹ The model of patient empowerment²⁰ in health education assumes the perspective that persons with a chronic disease like diabetes should learn about self-management options, so that they can make informed choices about their care and their lives. Assisting patients to assume responsibility for diabetes self-management is a priority. Success in the patient empowerment model is linked to the collaboration between patients and health care professionals in formulating the individual’s plan of care. However, the responsibility for diabetes self-management behaviors remains with the person with diabetes, depending on their developmental stage or current health status.

The Health Belief Model

The Health Belief Model has been useful in diabetes care and education to elucidate the variables that may have an impact on a patient’s adherence to a therapeutic regimen. The perceived threat of diabetes (its severity and the patient’s susceptibility to this disease) interacts with cues from the environment and a balance of the barriers versus the benefits of performing health behaviors.²¹ For example, if an elderly woman with type 2 diabetes is following few of the recommended exercise or dietary behaviors, it could be that she considers her condition as “only a touch of sugar” and so does not consider herself vulnerable to complications of diabetes. The Health Belief Model can prompt health care professionals to explore possible reasons for nonadherence to recommended regimens so that interventions can be altered. In summary, behavioral models have been beneficial in guiding diabetes education for interventions to promote and sustain changes in behavior.

THE HEALTH EDUCATION PROCESS FOR DIABETES

The educational process (Fig. 60-1) is cyclical, not necessarily sequential, and it involves at least four phases: assessment, planning (goal setting), implementation, and evaluation.⁵ The complexity of self-management activities for diabetes, especially when optimal metabolic control is a priority, necessitates the use of an education plan as a road map, a heuristic for both educator and for learner.

Assessment

Assessment is the data-gathering phase of the educational process, during which individualization of the content and the process for teaching is addressed. What to teach? How to teach it? Is the patient ready to learn? Is the patient able to make lifestyle changes? What are the desired outcomes of this education experience? Assessment takes time and reflective listening by the provider, especially when the learner is a new patient for the health care professional. Establishing good communication patterns with a patient is paramount for optimal diabetes care and for the subsequent educational process.^{22,23} Listening skills and being able to ask questions to elicit information are necessary skills for providers.

Areas to be explored for a comprehensive assessment include current level of understanding of diabetes self-management, family/social support, literacy level, health beliefs and cultural differences, past experience with the health care delivery system, coping skills and self-efficacy, and current health behaviors, among others. Though some health care settings have found paper-and-pencil as-

essment surveys to be efficient ways of collecting information, others are developing computer software for assessment. Health professionals can also use targeted interview questions to assess a patient's knowledge, motivation, and readiness to learn about specific topics. See Table 60-2 for examples. The data derived from these and other questions regarding diabetes self-management knowledge and skills must be used in moving the process forward to the planning phase.

Planning

This phase uses the assessment data to develop a collaborative plan with the patient for the educational process. For example, information about the patient's stage of readiness to change behavior can help to define the plan. Table 60-3 portrays the Stages of Change model¹⁸ applied to diabetes as a guide to plan interventions appropriate for the assessed stage. Using this behavioral model, for example, once a patient is assessed as being in the *preparation* stage for changing a particular behavior, specific behavioral guidelines should be given for this planned change in behavior. Other assessment data will be used to decide on one-to-one teaching sessions or group classes; involvement of family; or appropriate printed, video, or computer-assisted educational materials or age-related games. Educational sessions may not always be the first priority; some patients may need counseling for coping with a new diagnosis of diabetes or other life stressors prior to any teaching-learning occurring.

The *goal-setting* process can be part of the planning phase, as it specifies, first, a particular behavior in measurable terms; second, a

FIGURE 60-1. The process of health education is cyclical and moves through four main activities: assess, plan, implement, and evaluate.

TABLE 60-2. Targeted Interview Questions**Weight Loss**

- Why do you believe weight loss is important? Why or why not?
- Are you ready to try to lose some weight?
- What would you have to do to begin dieting for a small amount of weight loss?

Increasing Routine Exercise

- In what ways do you think exercise might benefit your diabetes control?
- Are you prepared to make time for an exercise program?
- What changes in your lifestyle will exercise require?

Blood Glucose (BG) Monitoring

- How do you think BG monitoring can be helpful for your diabetes control?
- Can you imagine yourself checking your BG at home at least two times each day?
- Are you able to start testing at least once a day this week?

time frame for attaining the goal; and finally, an appropriate reward for achieving the goal. When there is mutual agreement on a specific goal, then possible obstacles to achieving the goal are explored with the patient, with discussion of strategies to overcome the obstacles. Goal setting can be useful for specific diabetes management behaviors, for example, waiting 20–30 minutes after injecting regular insulin to begin eating a meal in order to match insulin action with food intake. Goal setting assures that both patient and professional have defined a mutually acceptable, reasonable goal, and since it is measurable, they will also know when it has been achieved. A goal-setting “contract” should be written down, with copies for both patient and provider.

The following is an example of a typical behavioral, goal-setting statement focused on decreasing the risk of hypoglycemia²⁴ when intensifying therapy in type 1 or type 2 diabetes to improve metabolic control.

Until my visit next month, I will increase my blood sugar testing to four times each day (before each meal and before bed) and will record the results to discuss with my doctor, nurse, or dietitian.

The patient had identified an obstacle to reaching this goal, that is, falling asleep while watching TV before testing at night. To overcome this obstacle, the patient and provider discussed placing the monitoring equipment at the bedside after testing her blood glucose before dinner, as a reminder of the need to do another test before getting into bed. It is important to define specific behavior changes, so that the challenges of the complex diabetes regimen can be viewed as realistic mutual goals and incremental change can be recognized and rewarded.

Although behavioral learning objectives for diabetes education are well established,²⁵ a variety of techniques and strategies should be considered in the planning phase. For example, in the Diabetes Control and Complications Trial (DCCT),²⁶ the goals for metabolic control were standardized, but the blood glucose management and nutrition management approaches were individualized within the protocols. The planned nutrition approaches included carbohydrate counting, the Total Available Glucose (TAG) system, and exchange lists for meal planning to optimize metabolic control.²⁷ The planning phase builds on the assessment phase for individualizing interventions to meet the needs of diverse populations with materials appropriate and sensitive to their cultures.²⁸

TABLE 60-3. General Guidelines for Applying Stages of Change to Diabetes Care

Stage of Readiness	Key Factors Associated with Movement to Next Stage	Treatment Do's at This Stage	Treatment Don'ts at This Stage
Precontemplation	Increased information and awareness, emotional acceptance	Provide personalized information. Allow patient to express emotions about his or her disease.	Do not assume patient has knowledge or expect that providing information will automatically lead to behavior change. Do not ignore patient's emotional adjustment to the disease, which could override ability to process relevant information.
Contemplation	Increased confidence in one's ability to adopt recommended behaviors	Encourage support networks. Give positive feedback about a patient's abilities. Help to clarify ambivalence about adopting behavior, and emphasize expected benefits.	Do not ignore the potential import of family members and others on patient's ability to comply. Do not be alarmed by or critical of a patient's ambivalence.
Preparation	Resolution of ambivalence, firm commitment and specific action plan	Encourage patient to set specific, achievable goals (e.g., walk briskly for 15 min at least 3 times a week). Reinforce small changes that patient may have already achieved.	Do not recommend general behavioral changes (e.g., “Get more exercise”). Do not refer to small changes as “not good enough.”
Action	Behavioral skill training and social support	Refer to education program for self-management skills. Provide self-help materials.	Do not refer patients to “information-only” classes.
Maintenance	Problem-solving skills and social and environmental support	Encourage patient to anticipate and plan for potential difficulties (e.g., maintaining dietary changes on vacation). Collect information about local resources (e.g., support groups, shopping guides). Encourage patient to “recycle” if he or she has a lapse or relapse.	Do not assume that initial action means permanent change. Do not be discouraged or judgmental about a lapse or relapse.

Implementation

The action phase of the educational process is when the individualized teaching plan is implemented. Some well-known challenges or barriers to implementation of the educational plan include:

- Lack of clarity about *who* will do the teaching.
- Lack of communication/documentation related to progress.
- Lack of time or priority assigned to the teaching–learning process by either educator or patient.

Strategies to enhance the patient's learning process incorporate many principles of adult education previously described.^{7–10} Active participation for the patient, incorporation of their life experiences, and allowing mastery of one topic before moving on to the next are examples of educational strategies in the implementation phase.⁴

Evaluation

Health education for diabetes self-management must focus on both *process and outcome evaluations*.²⁹ A *process (or formative) evaluation* is an ongoing assessment to provide valuable information for refining or altering the educational intervention. Patient attitudes, behaviors, knowledge, and skills should be evaluated to make adjustments in either the content or the teaching strategy. When barriers to achieving the educational goals are identified early, the educational program can be modified to overcome the barriers. The results of process evaluations should be shared; receiving timely feedback on individual progress is important to adult learners. Process evaluations for group education programs should be shared with all members of the diabetes education team, so that program improvements can be implemented by all educators.

An *outcome (or summative) evaluation* assesses goals attained or appropriate endpoints. These may include physiologic parameters, such as weight or metabolic control, as well as self-management skills, self-efficacy, coping skills, and knowledge.^{30,31} If goal setting has been used in the process, the endpoint has already been agreed upon by patient and health professional. When goals have not been met, the educational process cycles back to the assessment phase.

Ongoing evaluation of diabetes self-management skills and knowledge is very important. Patients may remember the utility information, for example, how to correctly draw up insulin, but they may forget the particulars of other, less frequently used information, for example, urine testing for ketones when ill. Reinforcement of information or redemonstration of self-care skills may be (and probably are) needed. Finally, the evaluation process in health education should recognize and provide positive reinforcement for even the seemingly small, incremental changes in behavior to promote long-term success.¹⁸

Documentation and Communication

The educational process should be continuous rather than episodic; it is simply a matter of the intensity of the process. This continuity of the process is supported when the education is documented and shared with all health care professionals interacting with the patient. When used consistently, computer records, chart forms, or checklists designed to easily document diabetes self-management education for individual patients can orient health professionals to the patient's progress in knowledge and skill for self-management.^{6,25}

Current level of motivation for self-management and specific health behaviors must also be documented to fully describe the education process.

CREATING A TEAM: EDUCATIONAL RESOURCES AND PROGRAM DEVELOPMENT

Content of Diabetes Self-Management Education

The goals and content of health education for diabetes self-management must be adapted to individual patient needs. Goals for diabetes education²⁵ can be described in two broad levels: initial or survival level education, and in-depth or continuing education and counseling. These broad levels are then delineated for type 1 diabetes, type 2 diabetes, and both gestational diabetes and pregnancy with preexisting diabetes. The *initial* educational goals are designed to address the most basic skills and knowledge needed to cope with newly diagnosed diabetes without a medical crisis. The *continuing* education goals are gradually introduced after the basic survival goals are achieved.

According to the recently revised national standards for diabetes self-management education programs, there are 10 content areas for consideration in educational program planning and for individualized education.²⁵ These include:

- Describing the *diabetes disease process* and treatment options
- Incorporating appropriate *nutritional management*
- Incorporating *physical activity* into lifestyle
- Utilizing *medications* (if applicable) for therapeutic effectiveness
- *Monitoring* blood glucose and urine ketones (when appropriate), and using the results to improve control
- Preventing, detecting, and treating *acute complications*
- Prevention (through *risk reduction* behavior), detecting, and treating chronic complications
- *Goal setting* to promote health, and *problem solving* for daily living
- Integrating *psychosocial adjustment* into daily life
- Promoting *preconception care*, management during *pregnancy*, and *gestational diabetes management* (if applicable)²⁵

Beyond the more traditional diabetes education programs, several new behaviorally oriented programs have been developed and continue to be studied, with promising results. Among these are Blood Glucose Awareness Training,^{32,33} coping skills training for diabetes,³⁴ and a patient empowerment program for those who have had basic self-management education.²⁰

Structure for Education Programs

Patient education can be provided through on-site services in health care facilities and medical offices or through external referral to health professional educators for specific services. The structure of the educational experience can vary widely within each model. Both models can be used to achieve educational goals for patients in a coordinated manner.²

Communication between the health care providers, the educators, and the patient must be maintained so a team approach to the education and care is not lost. The strength of a team approach,

whatever the model, is that multiple perspectives are drawn on to provide the education. But the challenge to the team is in delivering a consistent message to patients. Consistency is more likely to occur if providers and educators are familiar with the educational materials in use in their settings. If differences in opinion occur between the health care professionals (e.g., site selection for insulin injections or amount of carbohydrate to treat mild hypoglycemia), then they should resolve differences rather than confuse patients. Good verbal and written communication are the key to creating a health care team, whether or not the physical location is the same.

Data from the 1990 National Institutes of Health physician survey indicate that endocrinologists referred the vast majority of patients with diabetes to a nurse or dietitian. Over 80% reported that a formal diabetes education program was necessary for diabetes self-management. Only 41% felt that they could provide adequate dietary counseling for their patients with diabetes.³⁵ Glasgow and colleagues³⁶ suggested that active recruitment of patients into intensive education programs may not be a successful strategy for providing diabetes education, and they proposed incorporating diabetes self-management education into the medical office setting. Consideration of health education as a process may emphasize the need for careful planning to achieve a quality educational program in the office setting. Perceived sources of information about diabetes were reported by individuals over 18 years of age, as seen in Table 60-4. The largest proportion perceived their physicians as a source of information about diabetes.³⁷

Attempting to link education program targets (goals) and the interventions to meet those targets is an important example of the assessment and planning phases in a continuum. Peyrot³⁸ portrays some of these potential linkages in Table 60-5, based on various studies in health education. This provides a basis for planning interventions; however, definitive associations of interventions with targets has rarely been accomplished in the complexity of educational research.

Assessment of Needs and Resources

The health care delivery setting and health care financing can play major roles in decisions regarding whether diabetes education will be on-site or by external referral. Health professionals who may be

TABLE 60-5. Linkage of Education Targets and Interventions

Target	Intervention
Knowledge, beliefs	<i>Didactic education:</i> Increasing awareness of risks and benefits; helping patients know how to make appropriate self-care decisions.
Skill	<i>Demonstration/feedback:</i> Showing how to execute skills; observing performance, correcting errors.
Intentions	<i>Goal setting:</i> Establishing specific and appropriate goals that are ambitious but realistic; behavioral contracting to increase commitment.
Barriers	<i>Problem solving:</i> Helping patients find ways to overcome barriers to implementing intentions.
Self-efficacy, burnout	<i>Support/counseling:</i> Helping patients maintain positive emotional well-being.

Source: Reprinted with permission from Peyrot.³⁸

involved in patient education include nurses, dietitians, physicians, social workers, psychologists, pharmacists, or exercise physiologists, among others. Hospitals and other larger institutions are more likely to have a wider range of disciplines and educational resources available. However, as the size of the institution increases, the task of coordinating the patient education effort may become more complex.

Third-party reimbursement for patient education varies by state and type of insurance, adding to both health professional and patient confusion.^{2,39} In some regions, diabetes education or "self-management skills training" that is linked to medical care may not be billable as a separate service. In other instances, when education is provided in a nonhospital setting, the coverage may be limited or nonexistent. Coverage inconsistencies have led to efforts at the state and national level to mandate coverage for diabetes education and supplies, and by 2000 the majority of states had passed such legislation with varying results. These laws should assist patients seeking coverage for specific diabetes supplies and education by a provider of a quality diabetes self-management education program or service.

On-Site Education

Selecting the on-site (clinic, medical practice) education option involves a number of organizational decisions, including how educational services will be financed, the role and scope of practice of the educator, and the logistics of program planning. The diabetes education staff may be employed by the health care facility or provide educational programs and consultations on a fee-for-service basis. Smaller medical practices may find the consultative option more fiscally viable. Group practices, especially those specializing in diabetes, are more likely to find employing a full- or part-time diabetes educator feasible.

When diabetes education is provided on site, the medical group must consider many factors, such as mutually agreeable financial arrangements for the fee-for-service arrangement. Having a written contract often clarifies fee schedules that may be ambiguous. When diabetes education is offered on an on-site basis, there may still be a need for external consultation for patients with special needs. For example, many practices may be unable to include an exercise physiologist as part of the diabetes education and care team, but some patients with diabetes will need an external referral for such education. Patients with complications (e.g., visual impairment)

are also likely to need specialized educational services or social services.⁶ Communication and documentation of the educational process may be somewhat easier in the on-site model, as documentation can be placed in the patient's record immediately and various members of the diabetes care team (e.g., physician, nurse, dietitian) can collaborate with greater ease.

Referral for Education

Referring patients for diabetes education that is outside the medical practice setting is well suited to the needs of many medical practices providing care to patients with diabetes. The medical practice would not have to be organized to provide additional services requiring physical space and expansion of staff on site. The external referral model provides a wide range of options that vary from hospital-based programs to diabetes educators in private practice with a variety of backgrounds and expertise (e.g., nursing, nutrition, counseling). Hospitals may have freestanding units devoted to outpatient education, whereas other programs are located within the hospital complex. Much thought must be given, however, to assessing the quality of the educational services, as well as to the methods for receiving feedback about patient progress to enhance continuity of care. Educational services provided by referral must be thought of as a necessary extension of the diabetes team, and sharing records of these services will enhance continuity of care for patients.

Individual versus Group Education

Programs may be offered as group classes, individual consultation, or a combination of both. In one-on-one consultation, the identified needs of an individual patient can be addressed more easily than in a group setting. The patient's knowledge, skills, and beliefs can be assessed, and families and significant others can be included when beneficial. The content and time allotted to individual topics can be adjusted to needs. The evaluation can be by return demonstration of skills or discussion of topics.

Group learning, on the other hand, provides support and a shared learning experience.⁴⁰ Support groups usually focus more on emotional issues, whereas topical classes are more likely to address skills and knowledge. However, group education programs can be designed to address both areas. The patient mix in group programs needs to be considered, though there is in reality often not a choice. Patients newly diagnosed with diabetes may be overwhelmed if they are in a group with other patients who have advanced complications. When the treatment priorities differ greatly in a group, patients may feel isolated and confused rather than sharing a common bond. An adolescent who is facing difficulty adjusting to diabetes may feel little in common with older adults who may focus on coping with chronic complications. Overweight patients may focus on hypoglycemia rather than weight management, even when they are on dietary therapy alone. However, group classes are a vehicle for the peer support sought by many patients.⁴¹

ASSESSING QUALITY DIABETES EDUCATION PROGRAMS

New national standards for diabetes self-management education programs have been developed.²⁵ These standards have been used to establish criteria to evaluate the quality of formal diabetes education

programs for recognition by the American Diabetes Association (ADA). This recognition process involves a comprehensive written application, which is then peer-reviewed, to document that a program and institution comply with the standards. The following areas are included: needs assessment, planning, program management, communication/coordination, patient access, content/curriculum, educator qualifications, follow-up, and evaluation and documentation, among others. As of 2000, there were over 1000 diabetes education programs recognized by the ADA as meeting the national standards. Recognition is currently granted for a 3-year period. Requirements for renewal include an update of the application and documentation of staff participation in continuing education related to the diabetes education content areas or of a diabetes educator who maintains credentials as a certified diabetes educator (CDE). Other agencies besides the American Diabetes Association may soon also be authorized providers of recognition for diabetes self-management education.

Many practice settings, especially solo or small group practices, may find that referral to a quality diabetes education program is not feasible owing to location and other factors. However, there are other options available to assure that patients have access to diabetes self-management education. In such settings, patient education can be included with diabetes office visits. Careful planning for appropriate length of patient visits and educational resources, both print materials and audiovisuals, is necessary. Also, referral to outside qualified diabetes educators may be possible. An educational needs assessment can facilitate decision making regarding inclusion of education within a practice setting or planning for outside referral. The criteria used in the assessment should be based on needs of the patient, qualifications of the educator, the educational goals and techniques used, and systems for follow-up and communication about patient progress.

Qualifications and Scope of Practice for Diabetes Educators

The complex education and counseling needs of a patient with diabetes may be met by the skills of a variety of health care disciplines. Generally, diabetes educators are nurses and dietitians, but health education is also provided by physicians, pharmacists, social workers, psychologists, and podiatrists, among others. The credentials of any diabetes educator must be assessed on knowledge and experience in diabetes education, as well as discipline-specific qualifications. The certification program of the National Certification Board for Diabetes Educators assures that candidates are qualified to be certified diabetes educators (CDEs) by virtue of passing a certification examination, completion of at least 2000 hours of clinical experience in diabetes education, and having credentials in one of the clinical disciplines described previously or a master's degree in a health-related field. Recertification is required for CDEs every 5 years by retesting with the certification examination. In 2000, CDEs in the United States numbered over 10,000 health care professionals.

Factors that determine a diabetes educator's scope of practice include licensure and discipline-specific practice, individual knowledge and skills, liability concerns, and practice setting.⁴² Registered nurses (RNs) include those prepared by 2- and 3-year nursing programs and by university-based 4-year degree programs. There are also master's-prepared advanced practice nurses (clinical nurse specialists and nurse practitioners). A registered dietitian (RD) has a bachelor's or master's degree with course requirements in biochem-

istry, physiology, foods, nutrition, and psychology. Registration for dietitians is regulated by the Commission of Dietetic Registration of the American Dietetic Association and is on a voluntary basis. A growing number of states have licensure for dietitians, generally based on the criteria used for dietetic registration. Medical nutrition therapy for diabetes should be sought from RDs specializing in diabetes nutritional management.

Although the number of independent diabetes education practices have increased, educators' concerns about inclusion in third-party reimbursement, scope of practice, and liability tend to limit the number. Dietitians may be more likely to have independent practices, but many are not certified diabetes educators.

CDEs will vary in type and level of expertise. For example, some CDEs will be very familiar with insulin infusion pump therapy and adjustment of therapy to achieve metabolic control, whereas others may have more experience in teaching the visually impaired or in coordinating a hospital-wide inpatient program. Expertise in weight control techniques and behavioral interventions can also vary widely. An interview with a diabetes educator is beneficial to ascertain specific areas of expertise and philosophy of practice.

Education Program Materials

A program assessment must include assessing the needs of the target patient population for diabetes educational materials. The National Diabetes Information Clearinghouse maintains a directory of diabetes educational materials that are available from a variety of sources. A directory of patient education materials is also published by the National Diabetes Education Program (NDEP), the American Diabetes Association, and the University of Michigan Diabetes Research and Training Center, as well as by The Joslin Diabetes Center in Boston or The International Diabetes Center in Minneapolis.

The assessment of need for educational materials should address the following questions:

1. *What are the educational needs of the target patient population?* Programs designed for the elderly,^{43,44} for children,^{45,46} for adolescents,⁴⁷ or for disadvantaged populations have different content, as well as presentation, tone, and format.
2. *Is the information contained in the material accurate, up-to-date, and motivating in tone?* Consider the actions a patient may take based on the message. Minor misinterpretations may not pose difficulty, but other errors could have greater impact and result in increased risks for patients.
3. *Is the presentation appealing and acceptable to the target population?* Patients may find the layout and format unappealing. Some material may be unsuitable because it fails to consider how culture influences lifestyle. Other material may appear to be judgmental or condescending. Sources for appropriate materials are available.⁴⁸
4. *Is the information presented in a clear, concise manner?* Many materials provide too much information and may be overwhelming, whereas other materials may include more than one interpretation.
5. *Is the material practical and feasible to use?* Materials must be incorporated into the flow of the educational or medical program. For example, having educational videotapes available may not be feasible if no one is available to load or rewind the tapes.

6. *Is there a disparity in the targets for patient education materials, such that some populations in need are not addressed?*

HEALTH EDUCATION FOR DIABETES SELF-MANAGEMENT: PRESENT AND FUTURE

The challenges of living well with complex diabetes regimens have directed patient teaching toward the more comprehensive health education process for diabetes self-management that is prevalent today. Recognizing that provider teaching does not necessarily equal patient learning or a change in behavior has been an important step.

After the success of the DCCT,^{26,49} the importance of the team approach to diabetes care, education, and counseling has been widely discussed. However, the practicalities of delivering a team approach had to be worked through and resolved. Still, behavioral strategies place the patient in the center of the team: assisting patients to develop problem-solving skills; encouraging increased communication during office visits,^{50,4} through recordkeeping, and by telephone; and providing a forum for mutual goal setting between patient and provider. Although the diabetes care team need not be in one physical location, the delivery of integrated diabetes care through good communication among the medical, nursing, nutrition, behavioral, and other educational services is the important feature.^{1,2} The cyclical process (assess, plan, implement, evaluate) of diabetes self-management education may seem unrealistic for a busy practicing physician; however, the emerging educational technologies, innovative educational materials, and models for creating a team provide opportunities for diabetes patients and their health care professionals to work together toward optimal glycemic control and improved quality of life.

Acknowledgment. We are ever grateful for the early guidance of Dr. Harold Rifkin in the development of the diabetes education team at the Diabetes Research and Training Center of the Albert Einstein College of Medicine.

 - in atherosclerosis, 165, 166–167, 166f
 - immune mechanisms and, 171
 - nonenzymatic glycation in diabetes and, 170
 - oxidative modification and, 167, 167–169, 168t, 170
 - free radicals and, 847
 - autoantibodies against, 171
 - dietary, in nutritional management, 441, 441t, 442

- Low-density lipoproteins/cholesterol (LDL) (*cont.*)
 levels of in diabetes, 805, 806f
 glycemic control affecting, 806
 ideal, 810
 metformin affecting, 541
 thiazolidinediones affecting, 549
- Low-leucine diet, for leucine-induced hypoglycemia, 971
- Low-protein diet, in diabetic nephropathy, 447, 739–740, 739f
- Low-sodium diet
 in hypertension management, 816
 in nutritional diabetes management, 443–444
- Lower extremity
 amputation of, for diabetic foot, 849
 diabetic vascular disease in, 851–853, 851f, 852f
- LPL. *See* Lipoprotein lipase
- LY333531, PKC activity affected by, microvascular disease management and, 192
- diabetic retinopathy and, 656
- Lymphocytes
 antigen-specific, clonal selection of, 219, 220f
 development/selection of, 222–223
 in host defenses, 602
 abnormalities of in diabetes, 603–604, 603r
 receptors for, diversity of, 219–221, 221f
- Lys^{B29}Pro^{B29}–human insulin (insulin lispro), 492, 493–495, 493f, 494f, 501–502, 502f, 950
- in mixed preparations, 502
- in multiple daily injection (MDI) regimen, 503–504
- in twice-daily administration regimen, 502
- MA gene, lentivirus, gene transfer and, 198
- MacArdle's disease, 963
- Macronutrients, in nutritional management, 439–443
- Macrophages, diabetes affecting function of, atherosclerosis and, 170–171
- Macrosomia, maternal diabetes and, 623, 641, 642, 646
- Macrovascular disease. *See also* Atherosclerosis; Cardiovascular disease
 exercise/physical activity and, 474–475
 intensive diabetes management and, 918
 microvascular disease and, 171–172
 in older patients, 415, 416r, 420
 pregnancy and, 625
- Macula, 663
- Macular detachment, 669
- Macular edema (diabetic), 653, 667–669, 668f
 duration of diabetes and, 675
 hypertension and, 678
 photocoagulation for, 684
 vascular endothelial growth factor (VEGF) in, 657, 657f
- Maculopathy, 667–669. *See also* Macular edema
- Magnesium. *See also* Hypomagnesemia
 in diabetic ketoacidosis, 576, 576r, 577r, 578
 dietary
 in hypertension management, 817
 in nutritional management, 443
 in hyperglycemic hyperosmolar syndrome, 592r, 594
- Major histocompatibility complex, in NOD mice, 225
- Major histocompatibility complex molecules, 304r, 305f. *See also* Class I MHC molecules; Class II MHC molecules; Human leukocyte antigens
 overexpression of, in type 1 diabetes, 258
 T-lymphocyte recognition of, 221–222, 222f
 gene polymorphism and, 222, 223f
 restriction and, 222, 223f
- Male sexual dysfunction, autonomic neuropathy and, 796–799, 797f, 798r
- Malignant external otitis, 605, 900
- Malignant hyperthermia, in diabetic ketoacidosis, 584
- Malnutrition, profound, hypoglycemia and, 965
- Malonyl CoA
 in alloxan- and STZ-treated animals, 234
 in insulin synthesis, molecular studies of, 201, 206, 208f
 in ketogenesis, 16, 19, 20, 21f
 as metabolic signal in weight regulation, 154
- Malonyldialdehyde, in diabetic neuropathy, 757
- Maltase, acarbose/miglitol inhibition of, 543
- Mannitol, in nutritional management, 440, 440r
- MAOIs. *See* Monoamine oxidase inhibitors
- MAP kinase (MEK), p21ras binding and, 76
- MAP kinase-activated protein kinase-1 (MAPKAPK-1), in glycogen synthase regulation, 74
- MAPK. *See* Mitogen-activated protein kinase
- MAPKAPK-1. *See* MAP kinase-activated protein kinase-1
- Maple syrup urine disease, hypoglycemia and, 966
- Maternally inherited diabetes and deafness (MIDD), genetic studies of, 340
- Matrix-cell interactions, AGEs affecting, 186
- Matrix-matrix interactions, AGEs affecting, 186
- Matrix metalloproteinases, in diabetic nephropathy, 706
- Maturity-onset diabetes of the young (MODY), 267, 347, 351–354. *See also* Familial mild hyperinsulinemic diabetes
 classification of, 266r, 267
 genetic factors in, 351–354
 glucokinase mutations in (MODY-2), 33, 46, 202, 267, 351–353, 352f, 353f
 HNF-1 α mutations in (MODY-3), 33, 267, 353, 354f, 355f
 HNF-1 β mutations in (MODY-5), 267, 354
 HNF-4 α mutations in (MODY-1), 33, 267, 351, 351f, 352f
 NeuroD1/BETA2 mutations in (MODY-6), 267
 PDX1 (IPF-1) mutations in (MODY-4), 33, 267, 353–354
- MC3 receptor, in weight/food intake regulation, 157
- MC4 receptor, in weight/food intake regulation, 157, 158f
- MCP-1. *See* Monocyte chemoattractant protein-1
- MD-STZ diabetic mice, 234–235
- MDI regimen. *See* Multiple daily injection (MDI) regimen
- Meal-related (prandial) insulin, 488, 488f, 951
- Meals
 energy balance and, 151–154
 frequency/timing of, in nutritional management, 444–445
 signals for initiation of, 151–153
 signals for termination of, 153–154
 interaction with adiposity signals and, 158–159
- Mealtime hyperglycemia, prevention of
 in type 1 diabetes, 951
 in type 2 diabetes, 953
- Medicaid, health insurance available from, 975
- Medical illness, diabetic ketoacidosis and, 575
